This book is a powerful instance of the value of teaching a subject through a history of its development. It is in fact questionable whether any approach is so sound as that which rests current knowledge on a foundation of what is known to have preceded it. The perspective thus obtained is of the greatest value in bestowing a capacity for balanced judgment about the "facts" often so called, but really provisional findings, in the domain of science. Knowledge of this sort distinguishes the scholar and the savant from the crammer and the exploiter—the mastercraftsman from the common journeyman.

Boring's book is not only well documented but well written, and his method of giving his references in notes rather than dry lists ("nominal rolls," as they would call them in the Services) is worth imitating. The contents are very copious, and include accounts of physiological theories, such as the membrane theory of nervous conduction.

The summary of the present state of knowledge in each field is done with judicial impartiality. There is a concise and lucid statement of the principles of *Gestalt* psychology, and a fair evaluation of its influence. Where the author has made his own contribution, as he did to the controversy over sensory endings in the skin, he is not prejudiced. After covering the history of sensation and perception in each sensory field, including the visceral field, he discusses in a final chapter the nature of scientific progress. It is an interesting study in the social psychology of science. He indicates how scientific progress depends on instruments and techniques; insight, he points out, rarely can be independent of contemporary thought. The inertia of tradition is emphasized. "Men do not readily perceive the obvious when it contradicts their habits of thought. . . . Personal and social attitudes can constrain or divert thought. . . . There is a need for prestige, for self-consistency, and for conformity; even scientific men need to stand together; they shiver in scientific isolation." How well we know these limitations! The history of even the purest of sciences, mathematics itself, has not been free from them. Boring has some homely and less general admonitions. His warning to Harvard is one that we might all take to heart. "Sometimes," he says, "I fear that if Harvard does not give up trying to turn itself from an institution of learning into an educational institution, we may have a generation of professors whose duty it will be to disseminate information which they have not had time to acquire."

TREATMENT OF DISEASES OF THE HEART

Tratamiento de las Enfermedades del Corazón. By Dr. Luis Calandre. (Pp. 247. 25 pesetas.) Madrid: Ediciones Pegaso. 1942.

Dr. Calandre divides his book on the treatment of diseases of the heart into two main parts: in the first he describes the various available therapeutic measures, and in the second the more common types of heart disease and the appropriate treatment. In his introduction he states that there is a tendency to consider an accurate assessment of the functional capacity of the diseased heart to be more important than an exact anatomical diagnosis of the lesion present, and he contrasts the well-known type of case in which there are gross physical signs but the patient may remain well without treatment for years with others showing serious circulatory insufficiency but in which the lesion is difficult to diagnose. He emphasizes the importance of recognizing the effect of cardiac failure upon other organs and, equally, the effect that extracardiac disease may have upon the heart. The help to be obtained from special methods of investigation should never be neglected. The author gives first place in drug therapy to digitalis, which receives 25 pages, and a historical review notes that William Withering was the first to recognize its value in the treatment of oedema of cardiac origin. Digoxin is omitted from the list of preparations, and not all would agree that the tincture keeps well for several years. Strophanthus and squills are listed with digitalis as cardiac tonics, while under stimulants come camphor, caffeine, and adrenaline. Depressants include quinine and quinidine, atropine, nitrites, and also various organ extracts—e.g., padutin—the doubtful value of which Dr. Calandre neatly delineates by stating that their efficacy is not always appreciable. Among the sedative drugs morphine is stressed, the indications and contraindications for its use being clearly stated. The time-honoured prescription of valerian for cardiac and other neuroses is noted. Of the diuretics, while the value of the mercurials is appreciated, no mention is made of the rectal route of administration. The chapter on dietetic management is excellent. The second part of the book, comprising some two-thirds of the whole, not only describes the application of the therapeutic agents detailed in Part 1, but gives clinical descriptions of various cardiovascular diseases, together with their prognosis. Dr. Calandre does not hesitate to state when knowledge is scanty, aetiology is unknown, treatment is of no avail, or prognosis is hopeless. He does not indulge in theories lacking foundation. His book is full of common sense and of evidence of his experience, and should be read by anyone wishing to learn how heart disease is assessed and treated.

THE NURSE IN TRAINING

Nursing Life and Discipline. By Sheila M. Bevington, Ph.D.(Econ.). With a preface by Charles S. Myers, F.R.S., and foreword by Florence Horsbrugh, M.P. A Study Based on over Five Hundred Interviews. (Pp. 89. 7s. 6d.) London: H. K. Lewis and Co. 1943.

Even before the outbreak of war recruitment for the nursing profession was becoming a difficult problem. Dr. Sheila

Bevington has undertaken an inquiry into the reasons for this, in the course of which she confidentially interviewed 525 nurses and obtained their opinions. She admits that it was the more modern-minded matrons who agreed to her so doing, while the less progressive ones denied her entry. Despite this favourable bias it is clear from her data that things are far from right. One great improvement has been made by splitting the Preliminary State Examination, which allows of the first part being taken before entering hospital. Medical students are not expected to work at their preliminary subjects while doing ward work, and there is no reason why nurses should be submitted to this double strain. Yet this improvement met with strenuous opposition. But the gravamen of the charge is that while girls in other walks of life are increasingly treated as responsible adults, the nurse is still often encompassed by disciplinary rules which, however adapted for a bygone age, are certainly unsuitable, if not intolerable, to-day. Moreover, the probationer is often left in doubt as to whether she is a public servant, an employee, or a student. Actually she is all three, but the distribution between those roles is often obscure. Dr. Bevington has some constructive proposals to make, largely based on changing conceptions of discipline; but so long as the bullying methods all too common in hospitals are maintained many girls of an admirable type will fight shy of the nursing profession. Doubtless the ward routine is trying to the nerves, but it is significant that many Sisters can adopt a much more sympathetic attitude to the relations of her patients than to the probationer who finds herself in an entirely strange world. It is to be hoped that Dr. Bevington's carefully documented conclusions will not fall on ears deafened by convention and tradition. Even the material improvements foreshadowed in the Rushcliffe Report will not solve the problem without a still further internal change of attitude.

Notes on Books

Sir Frederick Banting, whose name will ever be associated with the discovery of insulin, lost his life on Feb. 21, 1941, in an aeroplane while on a mission concerned with research into medical aspects of flying. He died in his 50th year, but he was already a world celebrity in his earliest thirties. Few people in this country know that Banting had a gift for draughtsmanship and colour. He first became interested in art after the last war when he was struggling to establish a practice in London, Ontario. He came to see a kinship between scientists and artists and was willing to believe that the latter did research work too. He started to make sketching expeditions in 1927, and as the years passed he developed into a vigorous painter. Most of his work was painted on small birch panels, out of doors under all conditions of weather. "He was learning to simplify and to keep his colours fresh." The story is now told in an illustrated booklet, *Banting as an Artist*, by A. Y. Jackson, LL.D. (Ryerson Press, Toronto; 75 cents). This is published appropriately at a time when a special committee has held an exhibition of his paintings, drawings, and wood-carvings in the Art Gallery of Hart House, University of Toronto. The exhibition was the result of a suggestion by Prof. Barker Fairley, a former chairman of the Art Committee, after discussing the matter with Dr. C. H. Best, Banting's fellow worker, whose name is linked with his whenever the story of insulin is retold. This interesting pamphlet includes a catalogue of Banting's artistic output and a brief memoir by Dr. Frederick W. W. Hipwell, a fellow student and lifelong friend. Paintings lose much when reproduced in black-and-white, but we can well believe Dr. Jackson when he says of Banting's sketches: "The pleasure was in making them, in mixing up a lot of colours in a sketch box and all the adventures that led up to it, the freedom from responsibility, scrambling over unknown country, getting burned by the March sun, smoking a pipe before the camp fire, or the welcome at the little hotel and the good meals and looking over the day's work. Then all these things were put aside and there was no more time for painting, but the memories were there."

The Governors of the Royal Cancer Hospital, London, have authorized the re-publication of selected papers from that hospital and the associated Chester Beatty Research Institute. The volume consists of 484 pages, and includes 30 contributions which have appeared in various scientific journals, many of them no longer available as reprints. It is hoped that this volume will be the first of a series to be published annually. A limited number of copies are available at a cost of 16s. each, post free, from the Secretary, Royal Cancer Hospital (Free), Fulham Road, London, S.W.3.

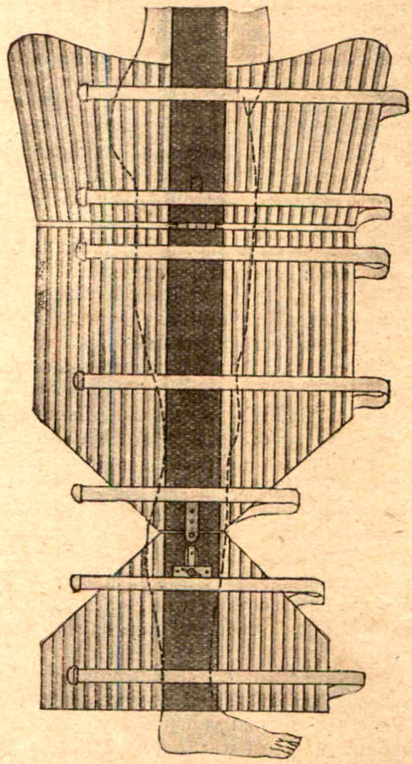
Preparations and Appliances

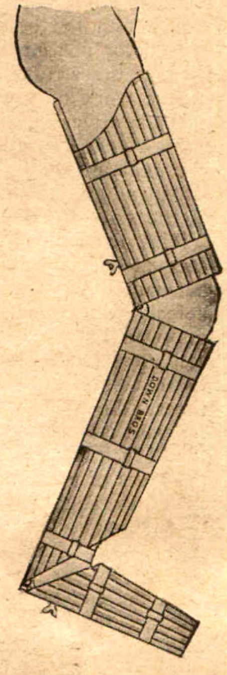
A UNIVERSAL FIRST-AID SPLINT

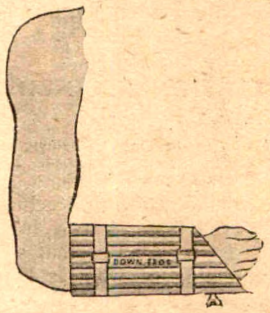
Dr. F. O'Sullivan (Harrow) writes:

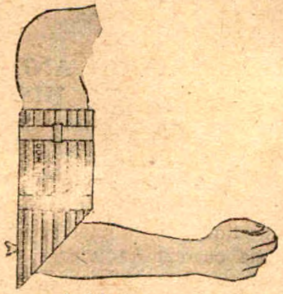
The following type of universal first-aid splint, recently designed by me, may, I think, help to facilitate the treatment of certain types of fractures of the lower and upper limbs. It can be employed for first-aid treatment of fractures of the femur (upper, middle, and lower thirds), the neck of the femur—acting as a modified long Liston—the patella, fibula and tibia, and the tarsus and metatarsus. It is possible to disarticulate the sections for treatment of fractures of the humerus, the radius and ulna, and the carpus and metacarpus.

The splint may be employed also in certain cases as a tourniquet: with suitable padding, no bandages are needed for its application, valuable time thus being saved. Its use does not interfere with x rays, so that diagnosis can be verified without removal. Another advantage of this type of splint is that it can be folded when not in use. The splint may be applied outside the clothes, and has been proved effective for most standard sizes.









The appliance is constructed of light wood, consisting of rigid back pieces with detachable hinges, which can also be locked. The sides are formed of strips of strong rounded lath, attached to firm strips of canvas, resembling cricketers' leg-pads, which can be rolled, and at the same time give firm adjustable support, laterally and anteriorly. The articulating ends of the splint have clamp screws and pins for the adjustment of angles. The splint is quick and simple in application, and its technique can easily be learned by first-aid students.

My grateful thanks are due to Mr. Kearsey, chief engineer to H.M. Stationery Office, who kindly constructed the first model for me, also the drawing details of the splint itself. The improved model has been made by Messrs. Down Bros. Ltd., who have kindly supplied the illustrations.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 10 1943

FROM BEVERIDGE TO BROWN

Not long after the Council of the B.M.A. had collected the views of a number of its committees on Assumption B of the Beveridge report, and had on the basis of these drafted a recommendation to put before the Representative Body, the Association was asked by the Minister of Health to form a committee to confer with him on the procedure of discussions to take place forthwith on a comprehensive National Health Service. The Minister of Health was at the same time taking similar steps with representatives of local authority organizations and of the voluntary hospitals. When it was clear that the Minister wanted to meet a committee representative of the profession, agreement with the Royal Colleges and the Society of Medical Officers of Health was quickly reached on the desirability of united action, and a committee, the personnel of which was set forth in the *Journal* of March 20, page 359, was formed. It has since been enlarged slightly by the addition to its number of a " truly rural " practitioner from Wales, of two representatives of non-teaching voluntary hospitals, and of a doctor in general practice to be nominated by the Society of Apothecaries, an ancient champion of the rights of the general practitioner. At the joint Conference of the Representative Body and the Panel Conference on March 31, and at separate meetings of the two bodies later on the same day, the representatives were asked to approve the composition of this committee. This approval was given, the Panel Conference recommending in addition that Scotland be asked to choose its own representatives, other than those already nominated by the Royal Scottish Corporations. The combined and separate meetings—the proceedings of the former are reported in this week's *Supplement*—also agreed that the Government's invitation to enter into discussions without commitment be accepted; and that these discussions should be conducted in the light of the undertaking that all members of the medical profession, including Service members, shall have an opportunity to express their views and to present them to the Representative Body, and that before negotiations open, and before proposals are submitted to Parliament, such proposals shall be considered by every unit of the Association's organization. The full text of the recommendation agreed to is given in the *Supplement.*

Those who took part in these meetings on March 31 are to be congratulated on the sense of unity they maintained amid a diversity of views on certain aspects of the situation they were confronted with. The action of the Executive Committee of the Council, for example, in forming a Representative Committee without referring the matter to the peripheral organization of the Association was sharply criticized by several speakers. These critics were disinclined to believe in the urgency of the situation. But it was soon made clear that the urgency was all on the part of the Ministry of Health. The Minister decided to get off the mark quickly. If those responsible for central executive action at B.M.A. headquarters had not shown equal alacrity, then the peripheral organization of the Association might well have asked its elected executive and appointed officials why they were not fulfilling their proper task of acting and leading. The central executive has the right to expect the confidence of those who have chosen it to conduct the affairs of the Association. And when it comes to dealing with the Ministry of Health it is well to be on the scene quickly. That the B.M.A. was on the scene quickly was a matter for congratulation, not for reproach.

It should be emphasized once more that the Representative Committee is not a negotiating body; it is not, that is to say, a body which is to arrange with the Minister of Health the terms and conditions of service in the new scheme contemplated by the Government. The committee will discuss, argue, advise, correct, and guide—but it has no power to enter into any commitments on behalf of the profession. No action will be taken before the whole profession has had full opportunity of reviewing the proposals and of making representations on them. For the Association's part, it is entering on these discussions, as Prof. Picken pointed out, prepared as it has never been prepared before. It has published, and just before the war brought up to date, its proposals for a General Medical Service for the Nation. During the war it has published the draft interim report of the Medical Planning Commission. Apart from anything else, the preparation of these reports has trained a number of men to deal with problems of medical organization and has taught them the craft of discussion round a table. It is this constant practice afforded by work in the Association's numerous committees that enables it to make a special contribution in the particular task ahead. A hint of what this task is was given by Mr. Ernest Brown, Minister of Health, in a speech on March 26, when, referring to group practice in health centres, to consultant and hospital services, he said: " We must commit to capable hands the duty of providing these services, by drawing together into a comprehensive whole the sometimes scattered and unrelated resources we already have, and by developing them wisely and well. The Government looks confidently to local government, with its long experience and its resilience in meeting the problems both of war and peace, to undertake this new responsibility." If this is to mean that the Government contemplates providing a national medical service by turning all doctors into local government employees, then it is likely that the discussions will last quite a long time—until in fact the Government changes its mind.

IS ANAEMIA PREVALENT?

It is no disrespect to the pioneers to say that the day has now passed when knowledge of the relation of anaemia to nutrition can be advanced by a medical officer working with an uncalibrated haemoglobinometer in an out-patient department or clinic. We now demand that the haemoglobinometer should be standardized in terms of oxygen capacity or N.P.L. specification.[1] Venous blood should be employed, to avoid the errors that are prone to occur in sampling capillary blood and to allow simultaneous estimation of the size and the haemoglobin saturation of the red cells. It is an advantage to estimate also the serum albumin, and the vitamin C content of the plasma or the white-cell layer. The diet should be assessed in terms of the total income per head, the money available for food per head, or, better still, the actual food consumed. It is desirable to know the incidence of recent infections, as well as the amount of menstrual and other losses, and the occurrence of pregnancy or abortion. Orr[2] has defined an optimum diet as one such that no improvement in nutrition can be effected by further supplementation. If iron supplementation is used to test the adequacy of the diet in iron, the iron must be continued for at least three months to allow the abnormal erythrocytosis produced by iron to subside.[3] In reporting results great care should be exercised in the use of words with strong associations, such as anaemia. It would be better to use colourless words such as hypohaemoglobinaemia and hypocythaemia, if they were not so cumbersome. To the clinician, anaemia means a haemoglobin level below 80%. It is therefore misleading to say that a group with an average haemoglobin level of 94% is anaemic, just because the normal average is 98.3%. The best method is to use statistical language and say what percentage of the group falls below the normal range (mean less three times the standard deviation). The clinician will perhaps understand the results better if he is told what percentage of the people were clinically anaemic—i.e., below 80% haemoglobin.

---

[1] M.R.C., Report to the Traumatic Shock Committee, *British Medical Journal* 1943, 1, 209.

If these stringent criteria are applied to a recent paper by Lucy Wills and co-workers[4] on anaemia in women and children on wartime diets, we must conclude that it is a great advance on much previous work in this field. It certainly contains some surprising and puzzling discoveries, though it is not possible to agree with some of the interpretations the authors have put on them. We will confine ourselves to the findings in the adults. The authors found that women working in factories have a higher haemoglobin level (94%) than London nurses and students of the same age (90.6%). London mothers of the hospital class have almost the same haemoglobin level (89.6%) as the London students and nurses, which is higher than that of nurses and students who have been working out in the sector for about six months (84.1%). The country nurses and students are obviously more anaemic than their London sisters. With the clinical notation of anaemia as a haemoglobin percentage below 80, the groups fall in a different order, the incidence of anaemia being 5% in the London nurses and students, 7% in the factory workers, 9% in the housewives, and 17% in the country nurses and students. The authors compare the mean haemoglobin values with Price-Jones's figure (98.3%) for normal nurses and female students in 1931, and argue that there has been a general lowering of haemoglobin values in the population. This conclusion does not, however, appear to be justified by the evidence.

Working-class women are a much more numerous section of the population than nurses and female medical students. There is no evidence that their haemoglobin levels ever were as high as Price-Jones's standard, and it must be said that the values found by Lucy Wills in 1942 do not suggest any general lowering of haemoglobin values throughout the population. No data were collected on the diet of these women. The authors would perhaps have been wiser to concentrate their attention and their conclusions on the findings in the nurses and female students. Here there has undoubtedly been a fall in haemoglobin. The authors have made a careful inventory of the diets, and it is clear that the women were not getting as satisfactory a diet as it is possible to get in wartime Britain. In fact, the country nurses and students were being undernourished, for they received only 1,662 calories, 47 g. protein, and 9 mg. of iron a day. They should have received over 2,000 calories, 65 g. protein, and 12 mg. iron a day. There is evidence that these unfortunate conditions were not confined to one particular sector. Even lower haemoglobin values were found in nurses in 1942 by Whatley[5] and Helen Wright.[6] Nursing has never been an easy profession; it has always had a high wastage rate. The Lancet Commission on Nursing in 1932 found that from 33 to 50% of probationers fell by the wayside. It seems that one of the ill effects of the war has been to expose women medical students in London to the same unnecessarily arduous existence as the nurse. But these evils are not peculiar to women students in wartime England. Pryor and Ferguson[7] in 1941 reported that of 364 Stanford women undergraduates, 145 had haemoglobin levels below 70%; in 90 the anaemia was hypochromic, and in 55 it was orthochromic.

Further analyses of the data presented would have made it easier to assess them fully. One of the dangers of this type of mass observation is that by pooling and averaging the data the exceptions are lost sight of, for the marginal fringe of observations might be more illuminating than the central core. Were the individuals with the higher haemoglobin values in each group successful in getting more food? And to what extent were the country students initially comparable with the town students? Is it not possible that the country group tended to be students who had previously lived in lodgings in London and perhaps consistently neglected their diet, whereas the London students were women who lived with their parents in London? This possibility is mentioned, and the high proportion of auxiliary nurses in the sector, because the findings are difficult to explain when taken at their face value. It is surprising that a difference of 6.5% in haemoglobin (i.e., 1/15 of the woman's normal store of blood) should have been brought about by six months' difference in diet between London and the sector. This corresponds to 300 c.cm. of blood, which is probably as much as or more than was lost at all the menstrual periods.[8] To put it another way, one in every eight nurses who went out in the sector developed clinical anaemia after a period which apparently averaged only about six months. This can hardly be explained by uncomplicated iron deficiency: the iron intakes in the two groups were 10.8 and 9.2 mg. respectively. The healthy woman has a reserve store of iron, and her daily needs are small in relation to the total amount of circulating iron. Then what was the deficiency in these young women? Was it in protein or in vitamin C or in total calories, or in all three? If it was protein deficiency, was this confirmed by estimation of the serum albumin, which is a more sensitive index of protein deficiency than haemoglobin?

Lucy Wills and her colleagues speak of the anaemia as a conditioned deficiency of iron. Even this expression appears to give too much weight to the importance of iron. One would expect that anaemia due to a conditioned deficiency of iron would be hypochromic, and that it would respond to treatment by iron. But in the few cases in which a complete blood count was done the anaemia was normocytic and orthochromic, and there was no evidence that it responded to treatment with iron. Indeed, recent work suggests that in the past far too much attention has been paid to the iron content of the diet, and emphasis should rather be placed upon obtaining diets optimum in other essential nutrients which have been shown to function in efficient iron absorption and utilization. Leverton and Marsh[9] have shown that it is quite possible for women to maintain iron equilibrium on as little as 7.2 mg. of iron a day, provided other factors such as calcium, phosphorus, and protein are adequate. All this evidence makes us unwilling to agree with Lucy Wills and her colleagues that "the most important factor in the aetiology of this anaemia is a low iron intake." Is there not an element of wishful thinking in this? It leads to the suggestion that the national diet should be fortified with metallic iron,[10] and we should have to feel a stronger conviction that anaemia was becoming more prevalent and that it was due to lack of iron in the diet before such a suggestion could be supported. The country would probably kick against a national loaf that turned the stools black. It would be difficult to give more than 15 to 20 mg. of Fe ion a day, and there is no evidence that so small a dose would have a curative effect on the 10% of the female population whose haemoglobin is below 80%.

Lucy Wills and her colleagues conclude that "the bearing of this anaemia on the health of the nation is of sufficient importance to call both for official action at the present time and for further investigation." Who are the officials who should act? The most obvious conclusion to be drawn from this study, and from an equally valuable investigation of public school diets by Widdowson and McCance,[11] is that the officials in charge of some of our hospitals and schools are not doing the best that can be done for their pupils in present circumstances. As Widdowson and McCance have pointed out, it is foolish to ask for extra rations or Government action when people who should know better are not taking up their full allowance of rationed and unrationed foods and are not even eating more potatoes. Much sound and practical advice has been given by the Ministry of Food, the Board of Education, the Industrial Health Research Board, and the Select Committee on National Expenditure, to mention only a few official bodies. It might be wise to follow some of this advice before asking for further action on a national scale. If the diet and health of nurses are below those of the general population, surely the first thing is to set our own house and garden in order.

PULMONARY CONGESTION AND OEDEMA

The death of Soma Weiss was a great loss to Harvard. For fifteen years he made extensive studies of various aspects of the circulation, and a short time ago there was published[12] an interesting review by him of some of the problems of congestion and oedema of the lungs. Broadly, the clinical causes of congestion and oedema are: (1) heart failure; (2) pronounced changes in pulmonary "haemodynamics" and/or capillary damage (infarct, pneumonia, drowning, irritant gases); and (3) diseases associated with retention of fluids in the tissues (beriberi, glomerulonephritis, and toxaemia of pregnancy). The causes may be combined. After a certain point has been passed oedema may progress rapidly; and the longer it lasts the more difficult it is to re-establish the physiological state. Congestion and oedema may be localized (as in pneumonia). In heart disease, congestion usually precedes oedema, which may be either pericapillary (interstitial) or intra-alveolar, or both. When caused by infectious diseases or chemical agents, on the other hand, oedema often develops without preceding congestion, and results from changes in permeability of the alveolar wall. Failure of the pulmonary circulation often occurs in the presence of an adequately maintained greater circulation. If pulmonary oedema persists, fibrosis and obliteration of capillary beds in the alveolar wall may supervene. Thus heart disease can cause first reversible and later irreversible lung disease. There may be much interstitial oedema without intra-alveolar oedema, and therefore without rales, as is observed in patients with left ventricular failure who have dyspnoea and a low vital capacity. Diffuse intra-alveolar oedema, giving bubbling rales, may be unilateral, and may involve only one lobe. In left ventricular failure there is severe impairment of the reserve functional capacity of the left ventricle as compared with the right. Therefore, under physiological stress, a serious imbalance between the functions of the two ventricles is apt to occur. In such circumstances paroxysmal dyspnoea (cardiac asthma) and transient pulmonary oedema associated with heart disease may cause gross disturbance of the pulmonary circulation within a few minutes or even seconds. If the balance between the two ventricles as regards equality of output is re-established, by decreasing arterial resistance or the inflow to the heart or both, the engorgement will persist, because the accumulated excess of blood and oedema remains trapped within the pulmonary circuit (and diffuses away into the lung tissues slowly). Repeated attacks of paroxysmal dyspnoea may therefore lead to progressive deposition of fibrin and connective tissue (looked upon in the past as "induration pneumonia"). In this instance the left ventricular failure is caused by arterial hypertension, but it may be associated with a normal or low arterial pressure, as in coronary thrombosis. *X*-ray appearances, Weiss says, indicate that the distribution of oedema varies in different types of congestive failure: in general heart failure it is usually basal; in pure left ventricular failure it is often hilar and perihilar. Congestion and oedema usually begin over the right lung, and remain more intense on this side (right hydrothorax usually precedes left hydrothorax). During and immediately after an attack of pulmonary oedema, various bizarre-shaped distributions of the oedema may appear. These *x*-ray changes may disappear within forty-eight hours, but obstruction of lymphatic drainage influences the persistence of oedema within certain areas. At times the appearances may be identical with those observed in tuberculosis or pneumoconiosis. Accumulations of oedema close to lung roots may imitate shadows caused by aneurysms or neoplasms; and in rare instances haemosiderin pigment deposits and surrounding tissue reactions in mitral stenosis may give radiographs imitating miliary tuberculosis or sarcoidosis. The *x*-ray differentiation of pulmonary oedema, infarction, and pneumonia and fibrosis is often difficult, particularly as pulmonary infarction is often associated with local or generalized pulmonary oedema.[13]

SCABIES ON THE SCREEN

The first showing of a film produced for the Ministry of Health on the control and treatment of scabies was given at a recent meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine. The film, in two reels, occupying about 35 minutes, is a masterly production, with photography and cartoon-work of a high standard and a spoken commentary which is all that can be desired. It is not intended for exhibition to the general public, but is an instructional film for medical practitioners, as well as for health visitors and the personnel of treatment centres. Dr. P. G. Stock reminded the meeting that the Ministry of Health had issued a memorandum on scabies, in which it had said all that it had to say on the subject, but he added that Dr. Henry MacCormac, remembering the experience of this minor pestilence during the last war, had been anxious that some means should be available for bringing home to practitioners more vividly than can be done in an official memorandum or lectures, the need for appropriate action in view of the probable increase in incidence in war conditions. Dr. MacCormac had succeeded in interesting the Ministry in the project and had himself supervised the filming. The result of nearly a year's work, with the disappointments and delays of film production, is a highly finished "documentary," as we suppose it would be called. We understand that Dr. Kenneth Mellanby supervised the admirable cinemicrography, and that in the production of the film valuable assistance was given by the Middlesex Hospital, where some of the "shots" were made.

---

[10] *Lancet*, 1942, **2**, 441.
[11] Ibid., 1942, **2**, 689.
[12] *Bull. N.Y. Acad. Med.*, 1942, **18**, 93.
[13] See also *Amer. J. Roentgenol.*, 1940, **43**, 305

The film begins with animated tracings which reveal the recent rise in the incidence of scabies, and then goes on to illustrate the life-history of the acarus. Some excellent cinemicrography shows the burrowings of the parasite in the skin, and the technique of its extraction with the needle. The ease with which scratching may set up secondary infections, such as prurigo, is demonstrated, and then the film turns to treatment and disinfestation. The patient is shown undergoing a preliminary bath (without disinfectant), followed by the application of a light coating of the slightly warmed benzyl benzoate emulsion, now recommended as a wartime substitute for sulphur ointment. The effectiveness of the emulsion in causing the death of the mite is quite dramatically shown. Finally two well-recognized figures appear on the screen, one a prominent member of the public health service and the other a well-known dermatologist, who reinforce the lessons of the film with short homilies.

The film was highly appreciated by a large audience, which afterwards turned to a discussion of the general question of scabies. It was pointed out by both Dr. A. M. H. Gray and Sir Arthur MacNalty that the present increase of scabies is not entirely a war phenomenon, but began to be appreciable about 1936-7. The incidence has, however, risen steeply during the war years, particularly among the civil population, and one officer from a London fever hospital stated that, whereas in 1940 scabies was found in 3.5% of all patients admitted, in 1942 the incidence had become 7.2%, or more than double. Dr. E. A. Underwood, medical officer of health for West Ham, said that at the beginning of 1942 three scabies treatment centres were established in his borough, and from that time until the present the total number of cases treated was just under 7,500, with 37,000 attendances. The average number of new cases was from 400 to 500 a month. Since benzyl benzoate was introduced the average number of treatments per case was 3.4, partly accounted for by the treatment of secondary infections. A point made in the discussion, as also in the film, was that scabies is not a disease contracted only by persons of unclean habits, but that the mites may find a home in the skin of any person.

MEDICAL FOLKLORE

Modern medicine is too heavily indebted to empiricism to dismiss off-hand any medical practices that have not an obvious scientific sanction. To the American Indians we owe, as Eric Stone[1] has pointed out, some sixty drugs that figure in our pharmacopoeias, while our debt to other primitive forms of medicine, such as the Assyrian and the Egyptian, needs no stressing. The contribution of primitive medicine to the total body of knowledge is so striking that it has led some observers, such as E. H. Ackerknecht,[2] to postulate an instinct in primitive man enabling him to select valid modes of treatment. Practices that persist over generations, though they may change unrecognizably in the process of transmission, deserve attention. If they carry the germ of a valid empirical observation, their study has its own justification. More frequently they are rooted in superstition, but understanding of the irrational is a rational study. At its lowest medical folklore is the emergence and persistence of irrational practices in treatment, but there are other aspects. The study of folklore in general has revealed an amazing similarity in highly complex beliefs and practices in widely separated human groups. The significance of such data in the study of the early phases of civilization is obvious, though it is well to remember that apparently similar practices and beliefs may have different roots. Medical folklore touches the history and current practices of medicine at more than one point, but the literature on it is not rich. In this country the outstanding contribution has been Dan McKenzie's *The Infancy of Medicine*, published in 1927, but it is due to the indefatigable labours of J. D. Rolleston that we now have a substantial collection of folk-practices in these islands and comparison with practices elsewhere. His paper on ophthalmic folklore,[3] recently published, rounds off similar studies in otology,[4] venereal disease,[5] acute exanthemata,[6] alcoholism,[7] pulmonary tuberculosis,[8] dermatology,[9] and medicine in general.[10] It is to be hoped that they will eventually appear in book form

QUININE SUBSTITUTES

That many doctors do not yet appreciate the extent of the quinine shortage is shown by the number of communications we receive advocating quinine sulphate for a variety of conditions. Materia medica days may, perhaps, be too far off even for the most recently qualified to recall that the great bulk of our quinine supplies come from the East Indies, now overrun by the Japanese. Be that as it may, quinine is evidently being ordered and/or prescribed in such quantities as to call for a notice from the Ministry of Health that synthetic substitutes are now available and should be used for antimalarial treatment. In a circular to all hospital authorities the Ministry states that these substitutes—namely, the *B.P.* preparations mepacrine hydrochloride (atebrin), mepacrine methanesulphonate (atebrin musonate), and pamaquin (plasmoquin)—may now be obtained from the manufacturers as follows:

Substitute	Manufacturer	Dose	Pack
Mepacrine hydrochloride	May and Baker	0·1 g. (tablets)	Bottles of 25, 100, and 500
" " ..	Imperial Chemicals	0·1 g. (tablets)	Bottles of 15, 100, and 300
" " ..	Boots	0·1 g. (tablets)	Bottles of 25, 100, and 500
Mepacrine methanesulphonate	May and Baker	0·1 g and 0.3 g. (ampoules)	Boxes of 6 and 25
" "	Imperial Chemicals	0·1 g. and 0·3 g. (ampoules)	Boxes of 6 and 25
Pamaquin	May and Baker	0·01 g. and 0·02 g. (tablets)	Bottles of 15 and 500
"	Imperial Chemicals	0·01 g. and 0·02 g. (tablets)	Bottles of 15 and 300

The Director of Medical Supplies, Ministry of Supply, Portland House, Tothill Street, London, S.W.1, will help in case of difficulty in obtaining requirements.

We announced on Jan. 16 last (p. 87) an Order (S.R.&O., 1942, No. 2668), which came into force on Jan. 5, prohibiting the use of quinine and its salts except as antimalarial drugs, and restricting the use of quinidine to the treatment of cardiac arrhythmia.

THE MEDICAL SUPERINTENDENT

HIS FUTURE POSITION AND FUNCTIONS

BY

W. J. T. KIMBER, L.R.C.P., D.P.M.

Medical Superintendent, Hill End Hospital

There seems to be every probability that the future will see the establishment of a form of national hospital service in which the general hospitals of the country will be linked up in some such manner as they have been in the Emergency Medical Service. There are a variety of ways in which such a service might be administered as between central and local controlling authorities, and much difference of opinion exists as to the most suitable of them. These are not matters which need be discussed here, but I propose to consider a problem which will remain to be decided in any case—that is, the internal administration of the individual hospital, particularly as it affects the medical superintendent. Since in some quarters the appointment of a lay rather than a medical superintendent is favoured, it will not be amiss to discuss what evidence there is in favour of a medical appointment to such a post.

Such hospitals as we are considering will be staffed by whole-time junior medical officers—residents—and largely by part-time paid medical staff, many of consultant status, and possibly some senior whole-time officers holding clinical supervisory and possibly teaching appointments. The advantages of general medical knowledge in co-ordinating and encouraging the activities of such a complex specialized group of workers are considerable, but administrative capacity is also essential. Most lay officers holding administrative posts of similar responsibility are chosen chiefly on account of their administrative capacity, while this has often been almost ignored when a medical superintendent is appointed. If this point were duly considered in filling such posts a medical rather than a lay appointment would be almost universally approved. Further arguments in favour of this contention are presented later on.

Functions of the Medical Superintendent

What, then, are the functions of a medical superintendent and what position must he occupy in the scheme of things to function successfully? The position held by a medical superintendent varies very much at the present time. In most mental hospitals and some others he is the chief clinician, besides being the executive head of all divisions of the hospital—medical, nursing, and lay. In other institutions we find him in medical charge, possibly also controlling the nursing service, through a matron subordinate to him but with a largely or almost entirely independent lay officer directly responsible to the governing body. In effect these conditions exist in many public assistance institutions with hospitals attached. In some of the E.M.S. hospitals the medical superintendent officially admits and transfers patients, etc., to comply with the Ministry's requirements, but has little, if any, authority in directing or controlling the medical work of the hospital. Various modifications of these examples may be found. The difficulties of each of these positions have been revealed during the war period, and for the most part have been met and overcome. They demonstrate that none of these schemes is suitable for use in a permanent organization, but all are useful in indicating what to avoid.

Whether control is vested in a central Government Department or a regional board or a local authority, the essential elements of hospital organization in any scheme for a national hospital service consist of:

1. A lay administrative body, representative of (or, possibly directly elected by) the inhabitants of the district, charged with the proper expenditure of the funds they control, and with the efficient running of the hospital in the interests of those they represent. Such an elected body or committee would be strengthened by the co-option on it of other members with local interests and also by some medical representation.
2. A professional body, the medical staff comprising individuals with varying degrees of professional skill and experience—of consultant rank, intermediate, and junior status.
3. Nursing staff.
4. Lay staff, including medical auxiliaries and clerical, domestic, and maintenance staff.

The relation of the medical superintendent to the nursing and lay sections of the staff is a matter of some importance, and affects both his position and his functions, but it is subsidiary to that which he occupies in respect to the medical staff, and will not be further considered here. Similarly, his relation to the junior grades of the medical staff may also be passed over, since it will depend on whether or not his functions and his position as regards the senior medical officers are satisfactorily determined. And here, lest I should be accused of overlooking the needs of that all-important person the patient, I would say that from an administrative point of view I regard him as being adequately provided for by his representative on the hospital committee or governing body, though I admit that in practice something more than this should be accorded him.

The medical superintendent would be responsible for ensuring that the policy of the board was carried out through all departments of the hospital. As chief executive officer he must serve the committee by interpreting its policy and seeing this implemented; but equally he must serve the medical staff and arrange that they are adequately provided with the means and conditions for carrying out their work. True, no man can serve two masters, but it is equally true that a house divided against itself cannot stand. Any successful scheme of hospital administration depends without doubt on the governing body's commanding the respect and confidence of its staff. With this the medical superintendent will not be faced with the difficulties of divided loyalties; without it, difficulties cannot be avoided.

A Link between Board and Staff

The medical superintendent, then, finds himself in the position of a link between the hospital board and the medical staff. He must also, if the time and money and skill lavished on a patient in the hospital are to have the maximum effect, see that there is an effective linking up between the hospital and the environment to which the patient is to return. The crux of the problem as regards the position of the medical superintendent lies in determining the precise meaning given to the terms "link" and "linking up" used in this context.

A hospital committee or board of governors constituted as suggested would command the confidence and loyalty of the medical staff; it would determine the general policy of the hospital and possibly, through a house committee, would supervise the major details of administration.

As a professional adviser the medical superintendent must keep the committee informed as to the medical needs of the hospital and as to the views of the medical staff on these matters. He may have to attempt to assess the merits of competing claims of different departments. Such a task must be accomplished by some means or other, and although the final decision will rest with the democratically elected hospital committee, that body will be advised in the last resort by its chief administrative officer, the superintendent, be he lay or medical. Under whatever system of control the future hospital may be run, this position will not be essentially altered. Even in a fully developed State Hospital Service, unless local representation and control be entirely done away with—an unthinkable contingency—many important decisions affecting the welfare of patients and the efficiency of the hospital will rest in the hands of the institution's own board.

Arguments in Favour of the Medical Superintendent

Herein is perhaps the strongest argument against the appointment of lay superintendents. A competent medical officer in this position will not only advise on particular issues as they arise, but will succeed in keeping his committee in close touch with current medical practice and progress, thus enlisting their interest and ensuring their capacity to maintain a high standard of efficiency. This is vital, and I would not rely on the medical superintendent alone in advising and instructing the lay committee. There should be a medical staff committee, whose recommendations would automatically be submitted to the governing body. The medical superintendent would, of course, be a member of this staff committee, but not necessarily, and probably not usually, its chairman. I would go further than this even, and provide for the direct approach to the hospital board, by personal representation, of members of the medical staff committee in any matters affecting their work. The usual method of approach, even if a report were submitted, would be through the medical superintendent; but on a resolution by the medical staff committee direct approach by representatives should be allowed. I would stress the point that such procedure should be regarded as a normal alternative, not one to be employed in the ordinary course, since it is more cumbersome and would delay the taking of effective action. Nevertheless, it should be looked upon as appropriate when certain matters of importance were at stake. It should not be regarded by the governors, the medical staff, or the superintendent as a challenge to the authority of the last-named.

It is not to be supposed that medical staff of consultant rank will be willing to serve in a hospital unless there is provided some such scheme by which to approach the democratically elected body managing the hospital, if need be over the head of an autocratic executive officer. Such provision would do much to dissipate the fear of bureaucratic tyranny, of which, though probably sometimes over-emphasized, a number of examples could be quoted.

A patient in a large hospital, it has been pointed out by Lord Horder, is likely to find himself in a position of some disadvantage, since there is a tendency for him to be successively subjected to the scrutiny of so many specialists that no *one* seems to be responsible for him as an individual, and, I would stress, as an individual in a certain environment. A medical as opposed to a lay superintendent could appropriately step in here. In doing so his attention would be directed to the needs of the patient as an individual getting ready for discharge and so for passing on to the almoner's department and the sphere of social medicine.

It seems unfitting that while all departments of a hospital, including the many newly established rehabilitation units where such exist, are under the direct supervision of a medical officer, the almoner's department, which makes the final and culminating effort of the hospital to re-establish the patient as a social unit in his environment, should lack such direct medical supervision and control. Here, surely, is an opportunity for the medical superintendent—who is in contact with all departments and who, if successful, must have secured the co-operation of all his colleagues—to complete for them this last service which the hospital is called upon to render its patients. In this way, I think, some advance over what has been accomplished in the past may be expected. "The best doctors of all time," wrote Weir Mitchell, "have been those who regulate the lives of their patients so that they may be restored to and maintain health." The present-day cry for social medicine is merely an admission that we have fallen short of this ideal; but, organized on the lines I have suggested, the hospitals should be in a much better position to achieve success.

Summary

The need is emphasized for a medical rather than a lay officer to co-ordinate the work of the hospital and interpret its requirements and the general medical position to a lay representative governing body.

The outline of a scheme whereby the medical staff can make their views clear to the governing body is explained and the advantages of this in securing the services of experienced staff of consultant status are stressed.

The special relation of the medical superintendent to the almoner's department is discussed, together with the advantages of his direct supervision of this department in securing a full restoration of the patient and in maintaining for him "positive health" as a social unit in the community.

At a meeting of the Joint Tuberculosis Council in February, Dr James Watt presiding, some discussion took place on the draft of the circular on the scheme for mass radiography which the Ministry of Health is sending to local authorities. Dr. Jessel said it was a technical report and dealt especially with apparatus, teams, and administrative problems. It had been agreed that the films should be viewed by one person, and a standard classification had been drawn up. On the question of allowances during treatment the chairman said the chief problem was that of the forms of tuberculosis for which these allowances should be paid. Dr. Sandison suggested that they should be paid if the patient was recommended by the tuberculosis officer for "a period of treatment specifically prescribed by the tuberculosis officer with the aim and reasonable anticipation of resumption of working capacity." Dr. D. P. Sutherland thought that the following words should be added to this definition: "and to patients in whom resumption of working capacity is unlikely, but who carry out the requirements of the tuberculosis officer necessary to prevent the spread of infection."

REHABILITATION IN CIVILIAN HOSPITALS

SURVEY BY MINISTRY OF HEALTH

Following on the report of the Interdepartmental Committee on Rehabilitation (the Tomlinson Committee), and impressed by the need for reducing industrial wastage caused by prolonged invalidism, the Ministry of Health is taking steps to improve and expand in civilian hospitals the methods of treatment grouped under the term "rehabilitation." With the greatly increased number of classes of patients for which the Ministry has accepted responsibility within the emergency scheme, the earlier provisions authorized in 1941 have proved inadequate, and the Ministry is arranging for their expansion as well as for their more effective use.

As a preliminary a survey is to be made throughout the hospital regions, and a circular has been sent to the regional and sector officers suggesting that the officer or his deputy with some member of the clinical staff should visit the larger hospitals in the area in order to ascertain what rehabilitation treatment is at present given and to consider the most practical means of effecting improvements. The visitors are expected to make their own comments on what might be reasonably practicable under wartime conditions, and it is hoped that those in charge of the hospitals will also make suggestions. A full and frank discussion is desired amongst all those concerned.

The general principles of rehabilitation as the Ministry understands them are indicated in Supplements 28 and 28A to E.M.S. Instructions, Part I (Red Book), and may be conveniently summarized as follows:

Type of Patient	Rehabilitation Required
In-patients—	
1. Bedfast	In ward
2. Ambulant	Whole-time in rehabilitation department
Out-patients—	
3. Unfit for work—attend daily	„
4. Unfit for work—convalescence at home	Report for instructions and progress
5. Fit for work	„
Annexe or auxiliary hospital—	
6 Light workers away from home	Whole-time group exercises and games
7. Heavy workers	„

One of the most important requirements is considered to be the designation in each hospital of a medical officer as responsible for rehabilitation treatment. It is also suggested that this officer and if possible other members of the medical staff might in some cases be encouraged to visit an efficient unit where rehabilitation measures are in use, and that similarly masseuses and other auxiliary personnel might benefit by a period of duty at such a unit.

Problems of Staffing

A difficulty to be faced is that of the restricted numbers of masseuses and occupational therapists to be obtained through the usual channels—that is, the Chartered Society and Dorset House School respectively—but it is hoped that some suggestions may emerge as to alternative sources of supply. The position with regard to physical training instructors is also difficult. It has been suggested that suitable men in the National Fire Service or Civil Defence Services might be made available as part-time instructors. Such an arrangement, of course, would not apply in hospitals, where partially trained instructors would not be fully competent to judge between the needs of different patients, but the services of such workers might be employed in the final stages of rehabilitation, as, for example, for men returning to work in heavy industries who merely need to be "hardened off." Yet another class of worker needed is the trained social worker, whose job it is to facilitate the return of patients to normal life by investigating and improving their home conditions and advising as to employment—an extension, in fact, of the duty of hospital almoners. The circular makes suggestions with regard to the accommodation for these purposes at hospitals and the use of annexes and convalescent homes. Owing to shortage of labour and material, the provision of new accommodation is at present out of the question, but with good will and enthusiasm it is thought that much can be done by using hospital space at present devoted to less important purposes.

A further point on which the Ministry of Health is anxious is the encouragement of interest in rehabilitation methods on the part of practitioners generally and for the benefit of patients suffering not merely from fractures but from all kinds of disease and injury. Here, we think, the Ministry is knocking at an open door. The question of rehabilitation has frequently been brought to the notice of the profession in these columns —most recently in a leading article on March 13—and there is little doubt that the general practising doctor is now aware of the importance of this subject. The measures now being taken are emergency ones to meet a wartime need, but out of them will be evolved the peacetime departments forming part of a comprehensive health service.

Reports of Societies

CLINICAL PATHOLOGY

Some sixty members and guests were present at a meeting of the Association of Clinical Pathologists held at the Westminster Hospital Medical School. Dr. S. C. Dyke was succeeded by Dr. A. F. S. Sladden as president, and Dr. C. E. Dukes by Dr. W. H. McMenemey as secretary.

Blood Diseases.—A number of haematological papers were discussed and much attention was given to the aid which sternal puncture affords in many cases where the clinical findings and ordinary blood examinations do not indicate a clear diagnosis. Dr. Dyke described two misleading cases. In a girl aged 21 the blood picture—30,000 white cells, 98% of mononuclear type —indicated leukaemia; a positive Paul-Bunnell reaction, however, and the appearance of the bone marrow, established a diagnosis of infective mononucleosis. In a male aged 65, 2,800 white cells, nearly all mononuclear, indicated aleukaemic lymphatic leukaemia, but peroxidase stain and the bone marrow clearly showed myeloid leukaemia.

Dr. E. N. Allott described the case of a woman with Raynaud's disease whose serum contained agglutinins active at 37° C. against Group O corpuscles. Quantitative absorption experiments suggested that in addition to the abnormal agglutinin in the serum there was also a deficiency of the ordinary Group O antigen in the corpuscles.

Diagnosis of Tuberculosis.—In a discussion on laboratory aids in the diagnosis of pulmonary tuberculosis Dr. A. S. Watts pointed out fallacies in the patch test: the possibility of degeneration of the patch material and hence the greater accuracy of the Mantoux test; the necessity for thorough cleansing of fat from the skin with ether or acetone before the application of the patch; the lack of response in skin tanned by sun and wind. Speakers stressed the need for examination of a 24-hour collection of sputum by a concentration method if early morning specimens of sputum failed to solve the diagnosis. For concentration, some laboratories preferred the "antiformin," others the "soda" technique. It was agreed that by neutralizing the soda deposit the final material adhered satisfactorily to the slide. Dorset egg medium should be included, or the exclusive use of media incorporating glycerin would result in a disproportionate selective isolation of human type. H. G. Close showed cultures of saprophytic acid-fast bacilli which had grown in 30 of 1,900 specimens (1.57%) of sputa inoculated on Löwenstein media. They were characteristic in that 2 to 4 weeks elapsed before the colonies became visible on primary isolation; on subcultivation they grew within "days" at room temperature. All his strains were of the pigmented, smooth, easily emulsifiable type, and were non-pathogenic to guinea-pigs.

Pemphigus Epidemics.—Dr. F. A. Knott detailed, in a survey covering one year, recurrent epidemics of pemphigus among the babies in a maternity ward, and of staphylococcal infection among the mothers. The many cultures of *Staph. aureus* were (according to general biochemical activity rather than in any one reaction) arbitrarily divided into three grades —A, B, and C. Grade A was the most vigorous in haemolysin, coagulase, and pigment production, and fermentation of carbohydrates. Numerous cultures from nose, hands, skin, vagina, breasts, and mouth enabled the infected children to be identified, as well as the carriers presumably responsible for the outbreaks. Grade A strains predominated in fluid from unbroken bullae. Exclusion from the wards of all mothers, children, and nurses yielding grade A staphylococcus gave effective control of the outbreaks. Grades B and C appeared to play a minor part or none in causation. Grade A strains were rarely, if ever, found in the dust or environment, and seemed to be transmitted from person to person. It appeared that infants' noses became infected from carriers on the staff, and then infected the mothers' breasts during suckling. Dr. E. H. Gillespie pointed out that staphylococcal typing was the only reliable method for identifying strains responsible for epidemiological infection. Techniques which depended on the rate of antibody absorption, even if they helped in distinguishing potentially pathogenic staphylococci, would lead to false incrimination of carriers. From the ensuing discussion it was clear that some maternity hospitals are not yet alive to the urgent danger of direct spread of infection from mastitis, pemphigus, and the like, in what the *Lancet* recently called "the staphylococcal nursery."

MEDICAL HISTORY OF THE WAR

At a meeting of the Section of History of Medicine of the Royal Society of Medicine on March 3, Sir Arthur S. MacNalty gave an address on "The Official Medical History of the War." Sir Walter Langdon-Brown presided.

Sir Arthur MacNalty spoke first of surgical writings relating to early wars, notably those of Ambroise Paré in the sixteenth century, William Harvey's clinical notes which were the only such record of cases in the Civil War, and John Hunter's service with the Forces in 1761–2, when he acquired the extensive knowledge of gunshot wounds embodied in his important treatise (1794) on that subject. The first official medical history of a war was British and concerned the Crimean campaign (1854–6), which was published in two volumes within two years of the cessation of hostilities. The first of those volumes dealt with medico-military matters in the individual corps, and the second with the history of disease, wounds, and injuries. It was produced on the initiative of Sir Andrew Smith, Director-General of the Army Medical Department, who explained in the preface how he had searched the records of previous wars in vain for guidance as to the care of the sick and wounded, and, because of his disappointment, he determined that his successors should not have the same difficulty.

Other medical histories were published by the French and the Russians. The Americans published a medical history of their Civil War, and the Germans a history of the Franco-Prussian War of 1870–1. An unofficial account of the Russo-Turkish War of 1877–8 was published, showing that the Russians then had an organized medical service, and the Bureau of War Affairs in Japan prepared a surgical history of the naval war between Japan and Russia in 1904–5. A volume was also published by the British War Office in 1908 on medical and sanitary reports from officers attached to the Russian and Japanese Forces in the field

The First European War

Of the many nations concerned in the war of 1914–18 only Great Britain and the United States published comprehensive histories. The Germans issued a medical and surgical history in nine volumes, but gave no account of their administrative arrangements, and the French Government published a report of surgical statistics. In Great Britain, within three months of the beginning of the war of 1914, arrangements had been made for standardizing Army records of casualties in such a way as to serve a statistical purpose. This provided the skeleton for the official medical war history. Sir Walter Fletcher and Sir William Osler had been anxious that preparation should be made for this history by special inquiries and collection of data, and in January, 1915, a Medical History Committee was set up with Sir Alfred Keogh as its chairman. Many schemes were set on foot, but that committee never met again, and in December, 1918, a new committee was formed to arrange for the actual writing, with Sir William Macpherson as editor-in-chief. The History was published in twelve volumes between 1921 and 1931, and had proved of great value in connexion with administration and other matters in the present war. In 1925 two volumes were published on the Australian Medical Services; the Canadian Government included in its official history of the war one volume on medical services, and the New Zealand Government did likewise.

All these histories had dealt mainly, and sometimes entirely, with the organization of medical services in relation to armies in the field. But the present war affected the civil population much more than did the wars of the past. It was also remarkable in that a large standing army had been maintained in this country, so that the medical problems of the Services' and of the civil population were closely intermingled. A number of new features in public health came forward—movements of population by evacuation, the creation of the E.M.S. with the administrative association of municipal and voluntary hospitals, which received both civilian and Service cases, the effects of intensive air raids, many medical problems in connexion with industry, also rationing and nutrition. The writing of a history covering these events entailed inquiries and investigations which could proceed only while the war organization was in being.

Projected History of Present War

A War Cabinet committee was set up to control official histories, and it was determined that the medical history should be part of an organized scheme and include the civilian as well as the fighting Services. An interdepartmental conference was held in 1940, attended by representatives of every Department concerned, and it was recommended that a representative editorial board should be set up, with himself (Sir Arthur MacNalty) as editor-in-chief. Mr. R. A. Butler, President of the Board of Education, guided the initial deliberations of the board, but as he was a prominent member of the Government and immersed in official work, it was realized that a successor must be found as soon as the History was in preparation, and Mr. C. E. Flowers, a member of the Advisory Committee on Official Histories, was appointed, and through him the medical branch was kept in close touch with the parent committee. The Directors-General would be regarded as editors in respect of their particular services.

The duties of the board included the supervision of the collection of material, the prevention of overlapping, and the selection of contributors. It had power to co-opt experts on special subjects and to consult with investigation committees set up by other bodies, notably the Medical Research Council. Government Departments gave active co-operation by furnishing reports and official documents relating to medical administration and to technical and clinical subjects. Close touch was maintained with the various bodies and persons whose work had any bearing on matters of interest for such a history. The Dominions and Colonies and the Allied Governments collaborated. Close liaison had been established with the National Research Council in the United States, which was collecting similar data, and there was an exchange of experience and information. Attention was also being paid to medical literature already published. A far-reaching organization was being built up at the new offices at 25, Victoria Street, London.

Sir Arthur MacNalty described the scope of treatment of the various medico-sociological problems relating to civil life which had come into prominence during the war. Each of the fighting Services would contribute its own section, giving an account of its medical organization before the war, its growth and increased functions during the war, and the medical aspects of the various campaigns. Certain problems would be treated at length in those sections of the history which were likely to be published earliest, so that wartime experience might be made available as widely as possible. Contributors were being asked to submit progress reports, because, of course, few monographs could be written until the war was over. Records should be made while the memory was fresh, and changes in methods of administration or treatment should be recorded when they took place. He indicated some of the headings in the sections of the technical volumes—war nutrition, physical training of recruits, effects of shipwreck, immersion and exposure, blood transfusion, effects of high-explosive bombs, blast and crush injuries, burns, plastic surgery, also epidemiology, venereal diseases, psychiatric conditions, industrial health, and rehabilitation. A special volume would be devoted to statistics. In conclusion he invited the help of the medical profession, upon whose whole-hearted co-operation the success of the History would largely depend.

Discussion

Mr. C. E. FLOWERS said that the History would be a vaster work than any similar record of previous wars. There were two dangers against which to guard—namely, omissions and repetitions The urgency of the matter lay in the fallibility of human memory. Unless facts were collected at the time reliance could not be placed on the accuracy of a narration. Col. YULE stated that detailed accounts from the war diaries of certain operations had been completed. The story of the Norwegian campaign was finished, and the story of the expeditionary forces in the Low Countries nearly so. The civil aspect of the war was being dealt with on its social side by Prof Hancock and on its scientific side by Sir Arthur MacNalty. Surg. Cmdr. KEEBLE pointed out that naval medicine as an organization was comparatively new; 1943 was the centenary year of medical commissioned rank. The difficulty in producing a history of this war so far as the Navy Medical Service was concerned was the system by which medical officers were scattered all over the world as isolated units in H.M. ships. Moreover, a number of records were lost, and the men with them, and in whatever was eventually produced there were bound to be large gaps. Records of operations at sea had been completed to the end of 1941, and in large part for 1942. Dr. SANDERSON remarked that his Ministry (Pensions) dealt only with an aftermath of the war, and in the last war was relegated to the 1931 volume. This time it was hoped to include this aspect somewhat earlier. Fl. Lieut. DAVIS said that the R.A.F. organization made for a somewhat parochial approach to the collection of material for a history, inasmuch as it was divided into commands and groups which became very much self-contained. Every medical officer in the Air Force was being encouraged to express his opinions, if necessary voice his criticism, or at any rate make some form of contribution to the History. The histories of some of the campaigns were completed. Mr. MELLOR, secretary of the official committee, said that he thought everyone was more or less convinced of the necessity for writing their contributions while the subject was fresh in the mind.

GIARDIA LAMBLIA INFESTATION

At a recent meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland, with Dr. P. T. O'FARRELL in the chair, Dr. S. J. BOLAND, Dr. O. FITZGERALD, and Prof. J McGRATH gave a report on *Giardia lamblia* infestation. The first case was that of an adult male with recurrent attacks of tetany, diarrhoea, and steatorrhoea, and loss of weight. *Giardia lamblia* were found in the intestinal contents but none in the duodenal contents nor apparently in the gall-bladder after magnesium sulphate. Blood calcium was depressed to 5 mg. per 100 c.cm. blood; there was definite loss of fat in the split form from the intestinal contents, and the absorption of glucose was prolonged. *X*-ray examination showed marked clumping and segmentation in the lower ileum after a barium meal, and these radiological changes were shown, by intestinal intubation, to be correlated with the presence of *Giardia lamblia* in the intestine. There was mild normocytic and normochromic anaemia. Treatment with atebrin cleared up all the symptoms and signs except for the radiographical changes in the intestine.

In the second case a young boy aged 5 suffered from recurrent attacks of abdominal cramps and diarrhoea for some two years. There was no loss of weight, and apart from the presence of *Giardia lamblia* in the stools no other abnormality could be found. *X*-ray examination showed some changes in the lower ileum, but otherwise the child was healthy. Treatment with atebrin led to complete recovery from the infestation, but the radiographical changes persisted.

Prof. J. McGRATH, who made the pathological examinations, stressed four points. (1) It was important to show that giardiasis had a pathological significance, and these cases helped to give an affirmative answer. (2) The infestation was most marked in the duodenum and gall-bladder. The passing of tubes showed giardiasis concentrated in the middle or upper ileum. (3) The difficulty of identification of the cysts in the faeces had been resolved by the modified de Riva concentration method. (4) Atebrin (mepacrine hydrochloride) was an effective therapeutic agent.

Dr. OLIVER FITZGERALD, in reply to some questions, observed that if blood was present in the stools in any quantity *Giardia lamblia* were likely to be absent. The length of treatment was five days, 0.1 g. of mepacrine being given three times a day.

Prof. McGRATH replied that the concentration method described would show small numbers of giardia cysts in the faeces; by the use of this method the effectiveness of atebrin had been demonstrated. In giardia infestation damage was almost entirely limited to the mucous membrane. Giardia infestation occurred perhaps in early life; and a certain amount of damage was done to the mucosa of the intestine, particularly the ileum. This damage would persist and produce a partial failure of the absorption area of the small intestine; even if the giardiasis was cured the damage to the ileum remained. Early treatment of giardia infestation would prevent the extension of the damage and recurrence of these cases.

Correspondence

Planning for Treatment of Head Injuries

SIR,—Important and controversial issues are raised by Brigadier Hugh Cairns (March 13, p. 313) and also in the papers of Symonds and Russell and of Guttmann quoted by him and recently published elsewhere. Many pronouncements on the closed head-injury problem, in eagerness to prove how bright is the outlook, are guilty of a considerable syllogistic error. A follow-up of an unselected series of hospital admissions shows a high percentage returned, with satisfactory efficiency, to their work (Russell). It is too often assumed that this shows that a better "prognosis" is present in such cases than had previously been thought. Insufficient care is taken in differentiating between (1) the expectation of return to work and (2) the true prognosis of the injury which (in the words of the *Oxford Dictionary*) is "a forecast of the course of the disease." "Prognosis" is the corollary of "diagnosis," and, like the latter, applies to clincial manifestations and is independent of return to work. Thus, during a remission a sufferer from disseminated sclerosis may return to work without the prognosis being affected. Yet we see Guttmann publishing a paper, "The Prognosis in Civilian Head Injuries," in your issue of Jan. 23 last (p. 94) which, far from dealing with prognosis, is solely concerned with return to work. Guttmann is conscious, almost as an afterthought, of his illogicality, and, at the last moment, tries to retrieve himself by the illuminating remark, "The social prognosis [*sic*] is not identical with the medical prognosis," and proceeds to admit, with damaging reluctance, that some patients complained of headache, giddiness, and mental impairment, but that they "were able to adjust themselves to their symptoms" and that these "did not prevent them from returning to their previous work and doing it efficiently and willingly." We know that sufferers from severe post-concussional symptoms can, if of good stuff, often return efficiently to work even if the prognosis for recovery from symptoms is bad. Confusion must not be brought in by misusing the word "prognosis."

In an 18-months follow-up Major W. Ritchie Russell (Oct. 31, 1942, p. 521) found that about 40% of his patients still had symptoms. This points to a fairly serious prognosis for symptomatic recovery when we consider that his series doubtless contained many mild cases. In their series of Service cases Symonds and Russell (*Lancet*, 1943, **1**, 7) found 20% invalided and the remainder returned successfully to duty. No inquiry was made as to whether the 80% were symptom-free. It was apparently assumed that they were (a dangerous assumption), because the authors say: ". . . The prognosis is cases of accidental head injury in the Service personnel is usually good." This, of course, does not follow at all; the prospect of return to duty may be good, but not necessarily the prognosis for symptomatic recovery. Russell, with some naivety and unconscious reflection upon the cerebral requirements of the Army and of a stout section of it in particular, admits this when he says elsewhere in his article above quoted: "A slight degree of intellectual impairment often causes no noticeable disability to the private soldier, unless his previous intelligence was low. Transfer to the pioneer corps may sometimes be a satisfactory method of disposal." What of those pioneers who knocked out German tanks in Boulogne with their spades? The danger is that though "intellectual impairment" may produce no great disability in a private soldier (or even in far higher ranks) on garrison duty in England it may have a dire effect in emergencies and under stress on the battlefield. It is this well-known liability of those who have suffered serious head injury to break down under unusual or exceptional strain, even though they may be doing work well with which they are familiar, that makes it so important not to confuse efficient return to such work with a good prognosis.

One would like to see Symonds and Russell carry out a symptom follow-up in a similar series of Service cases and tell us what symptoms they find, especially among those back at duty. The questionary would need to be carefully composed to get the best results. It is probably misleading and incomplete to rely, as Guttmann did (*Lancet*, 1943, **1**, 10), on one symptom only, such as headache. I have found it useful to begin with a very general question: "Do you feel the same man that you were before the accident or have you never quite fully recovered from it?" It is surprising how often the reply to the first part of this question is in the negative, although the man may find it difficult to particularize his symptoms. The second question should be, "If you don't feel the same man, what do you feel wrong?" Only when these general questions have been answered should particularization begin. Sometimes a man, made of good stuff, will assert with pride that he feels fully restored, but when family or friends are questioned they are emphatic that he has never fully recovered. In a complete questionary the views of others should always be obtained. I feel that an inquiry on the above lines, confined to serious cases with unconsciousness or anterograde amnesia for more than 24 hours (for to include mild cases only confuses the issue), and carried out, say, 18 months after injury, would not produce such a bright picture as do these return-to-work studies.

As Cairns has said, the nature of the familiar post-concussional syndrome still remains a matter of controversy. Russell seems to regard it as largely psychogenic, while Cairns (*Proc. roy. Soc Med.*, 1942, **35**, 200) plumps for the physical basis. Jefferson sits, statesmanlike, exquisitely balanced on the fence: "We must beware, also, of the danger of coming to regard all who have had a head injury as neurotic, though it would not be wrong to regard all of them, as I believe we do, as potential neurotics" (ibid.). After that he can certainly come down on whichever side he fancies! The fact, I think, is that the clinical difference between the symptoms of traumatic anxiety, psychogenically determined, and those of the mental state directly produced by the cerebral injury is often very difficult to discern. Yet it is most important to make this differentiation. The psychological picture of cerebral injury seems one of diminution in intellectual power associated with loss of inhibition over lower mental function, so that the primary emotions, in McDougall's sense, are much exaggerated, the picture resembling that of other organic conditions, such as cerebral arteriosclerosis, sequelae to cerebrospinal meningitis and encephalitis lethargica. This is commonly shown by the violent and hasty temper to which many patients confess. Whining and peevishness are common in the neurotic but not towering rages, for which he has not the stomach, and this point is of occasional diagnostic value. So also is, of course, the organic diminution in the power of recent memory. Symonds has pointed out that chronic symptoms are commoner after head injury in those with a psychopathic personal or family history, but is this greater chronicity psychologically or physically determined? Probably physically, more often than not. A little loss in the power of the highest level of cerebral function, which is more vulnerable than lower levels, as a result of injury will make more pronounced an underlying neurotic state, just as an unstable person becomes more unstable as cerebral arteriosclerosis creeps on.

A final point of importance, I feel, is in connexion with the issue of the hour—rehabilitation. By all means "rehabilitate" the psychogenic traumatic neurotic for all you're worth, but there will be a very definite limit to the amount of rehabilitation possible for those with neuronal destruction. More productive results will probably follow skilled and detailed attention to "placement" or "disposal" (or whatever the favourite non-humanitarian word of the moment may be), rather than obstinate persistence in the uninspiring regimen of "netball, leather work, and rounders" in a rehabilitation centre. But it will need to be more carefully studied placement than merely "transfer to the pioneer corps."—I am, etc.,

London, W.1. T. ROWLAND HILL

Calorie Control

SIR,—I have followed the correspondence about calorie control with much interest, and agree with Dr. Lawrence and Dr. Fletcher in their comments. Dr. Wauchope has carried out a seven-day experiment on a diabetic patient and thinks that the result supports Dr. Crooke's claim. Unfortunately, her patient was very unbalanced, as the fasting value of the blood sugar varied from 343 to 68 mg. per 100 c.cm. Dr. Crooke's experiments were also carried out on a very unbalanced patient, as the fasting value of the blood sugar varied from 400 to 150 mg. per 100 c.cm. I do not think that any conclusions can be drawn from these results. To prove Dr. Crooke's hypothesis a patient should be selected whose fasting blood sugar is between 90 and 120 mg. per 100 c.cm. each day of the experiment, and he should have a dose of ordinary insulin night and morning and not one of P.Z. insulin, as it has such a delayed action. The effects of the diets must be watched for two or three days with alternate periods of the standard diet. These experiments are time-consuming, which perhaps explains why Dr. Crooke has not been able to carry them out in wartime, when laboratory technicians are few in number.—I am, etc.,

London, W 1 George Graham

Effect of *p*H of Blood on Haemolysis

Sir,—We have read the recent article by Lieut.-Col. Felix Smith and Capt. R. Winstone Evans (March 6, p. 279) with interest. In their discussion on the possible effects of changes in *p*H on haemolysis the authors mention work by Israëls on paroxysmal haemoglobinuria. They do not give a reference, but presumably this refers to a study made by one of us (J. V. D.) in 1937 on a patient suffering from chronic haemolytic anaemia with nocturnal haemoglobinuria ("nocturnal haemoglobinuria" or the Marchiafava-Micheli disease), an account of which was published subsequently in collaboration with Israels and Wilkinson.[1] This paper is, in fact, referred to later by Smith and Evans, who add inaccurately that a decrease in the *p*H of blood was demonstrated during sleep. No such claim was made, but the review by Kleitman[2] was quoted as authority for the statement. In nocturnal haemoglobinuria the *p*H of the blood is not abnormal, but it can be shown both *in vivo* and *in vitro* that a fall in *p*H will increase haemolysis and vice versa. A far better and more complete account of this disorder was published later in America by Ham.[3] This author studied the effects of the administration of large doses of alkalis to two patients. There was a transient inhibition of haemolysis, but Ham concluded that the use of alkalis was unwise, for cessation of treatment was complicated by severe haemolytic episodes.

The observations of Smith and Evans on the changes in osmotic fragility produced by alterations in *p*H are not new; the effect of variation in CO_2 content has been known for at least thirty years (Butler[4]), and the changes in cell volume have been carefully worked out by Hampson and Maizels.[5] Moreover, as the interrelationship between osmotic fragility *in vitro* and haemolysis *in vivo* has for long been a subject for debate, the tacit assumption that small changes in fragility produced by alkalosis are responsible for inhibition of haemolysis in blackwater fever cannot be readily accepted.

In their reference to the treatment of malignant tertian malaria Smith and Evans write that "slight jaundice associated with albuminuria is also an indication for stopping quinine." Both these signs are not uncommon in malignant infections, and are a feature of the "bilious remittent" type which, untreated, may end in death. It is possible that the authors prefer in such cases to replace quinine by some other antimalarial drug, but in the absence of any statement to this effect their implication that treatment should be suspended is both unjustifiable and dangerous. Furthermore, if the authors claim such cases are likely to develop blackwater fever they are in fact coming very near to implying that a pre-blackwater fever state can be recognized. Slight icterus and albuminuria have, however, no more claims to be portents of blackwater fever than have the classical textbook signs which the authors failed to find in their own cases.

Finally, the work of Fairley[6] renders no longer tenable the seventy-year-old belief that haemoglobin liberated by haemolysis undergoes conversion in human plasma to methaemoglobin.—We are, etc.,

J. V. Dacie.
F. Murgatroyd

Gastro-enteritis in Infants

Sir,—In the *Journal* for March 27 (p. 371) there is an article entitled, "A Standardized Plan for Treatment of Gastroenteritis in Infants," by Drs. Field, MacCarthy, and Wyllie, which I have read with great interest. They open the article with these words: "Following an outbreak of infantile diarrhoea and vomiting at a base hospital shortly after the onset of war, with the very high mortality of 80%, certain strict prophylactic measures were taken and a schedule of treatment formulated." The authors keep strictly to the title of their article and deal only with treatment, which they describe lucidly and which should prove most useful. Nevertheless, if I may say so, the interest and value of the article would have been greatly enhanced if the authors had stated what, in their view and if ascertainable, had been the cause of this outbreak. The terms "gross sepsis" and "parenteral infection" are used, but no indication is given of the nature or incidence of these illnesses or parenteral infections. No post-mortem findings or other investigations are given, and without these, in my view, no accurate statements about the presence or absence of parenteral infection can be made.

The authors divide "relapses" into two groups: (1) those occurring soon after the original illness, and (2) those occurring after convalescence had been established. In my experience "gastro-enteritis" occurring in hospital is almost invariably the result of parenteral infection, the commonest being upper respiratory infection leading to otitis media and possibly mastoiditis. The treatment which the authors so admirably advocate resolves itself into two methods: (1) reducing the amount of food, and (2) the administration of parenteral fluids, both of which are well recognized and generally accepted for gastro-enteritis in infants; but is it as well appreciated as it should be that such treatment is, in a considerable proportion of these cases, purely symptomatic?

In an annotation in the *Journal* of Jan. 2 (p. 19) the causes of infantile mortality are discussed and the following statements made: (1) "In the period after the first month the chief causes of death were infective conditions, which caused death in 90 out of 112 cases in which an opinion could be given." (2) "The relatively small number of infant deaths attributable to gastro-enteritis may be surprising to those accustomed to assume that diarrhoea and vomiting mean primary infection of the alimentary tract. That infection of the respiratory tract is nowadays—i.e., with the disappearance of 'summer diarrhoea'—the more serious problem needs repeated emphasis. . . ." These views coincide almost exactly with my own opinion and experience of this problem, and I was gratified to see them given such prominence in the *Journal*. If these views, which possibly explain the success that attended the preventive measures employed by Drs. Field, MacCarthy, and Wyllie, are correct—and I think they are—then the problem of parenteral infection is obviously one of the greatest importance to those having care of infants, especially infants in hospitals and institutions.

I trust the authors of this paper may see their way to embark upon a second article in which details of the points I raise will be dealt with.—I am, etc.,

Liverpool E. C. R. Couper.

Anaesthesia for Laryngofissure

Sir,—Mr. T. E. A. Stowell (March 6, p. 302) deprecates the use of trilene on the ground that it will decompose into phosgene if the diathermy cautery is employed. Dr. C. B. Lewis in his excellent memorandum (Feb. 6, p. 162) distinctly stated that the trachea was packed off around the catheter so that no anaesthetic vapour could be in contact with the spark. Even if it were, the amount of phosgene (as in the case of chloroform vapour) would be negligible. The only danger of phosgene is to the surgeon who is such an inveterate smoker that he continues to indulge his habit while actually operating. Under these circumstances he can inhale dichloracetyl chloride, carbon monoxide, hydrochloric acid gas, and phosgene. Whether this method of suicide is preferable to the more rapid disintegration which may follow the same practice with ether vapour is a matter for the surgeon himself to decide.—I am, etc.,

St Albans C. Langton Hewer.

[5] *J. Physiol.*, 1926–7, **62**, Proc. 16.
[6] *Quart. J. Med.*, 1941, **10**, 95.

SIR,—Having read with interest Dr. C. B. Lewis's medical memorandum (Feb. 6, p. 162) describing his anaesthetic technique for laryngofissure and Mr. Lionel Colledge's criticism (Feb. 20, p. 230), I should like to submit a method which I have used in my last four cases with satisfactory results.

Bearing in mind the necessity for establishing a light anaesthesia with rapid return of cough reflex, and for using a drug of minimal toxicity, non-irritant, and non-inflammable (in case diathermy is used), I chose the intravenous method and venesetic (sodium thioethamyl). This I find to be less toxic and less depressant to the respiration than other similar reagents. In premedication opiates were avoided, a small dose of seconal 2 to 5 gr. being given half an hour before operation. Induction was carried out with 5 to 8 c.cm. of 7.5% solution of venesetic. Then a cannula was inserted in the internal saphenous vein at the ankle and a glucose (5%) saline drip established. Immediately distal to the cannula a hypodermic needle was inserted obliquely and connected to a two-way syringe, which was strapped to the dorsum of the foot. Anaesthesia was maintained with 2 c.cm. of venesetic every 5 to 20 minutes. The throat was sprayed with percaine 1 in 200 in order that a Phillips airway should be tolerated. In one case with a large growth and stridor an endotracheal tube was necessary and passed under direct vision. Carbogen or oxygen could be given by this tube.

The advantages of this method are: (1) The anaesthetist and his impedimenta are out of the way of the surgeon. The pulse in the dorsalis pedis artery can be as useful as the superficial temporal. (2) The anaesthetic is not conducive to congestion or haemorrhage, is non-irritant to the respiratory tract, and respiratory depression is minimal. (3) If tracheotomy is favoured by the surgeon, as was not so in my cases, this may be done by him after induction. (4) The cough reflex is depressed but returns rapidly. A disadvantage occurring in one case was a mild thrombophlebitis of the internal saphenous vein used.

In three of my cases preliminary laryngoscopy had been done under venesetic and laryngeal percaine, and observations of the patient's reaction to this "preliminary canter" were of much use at operation. The patients liked the intravenous anaesthetic and were pleased and relieved to know that they would have it for the major operation. Admittedly, no definite conclusions can be drawn from four cases, but these were so satisfactory to patient and surgeon that I propose to continue to use this method for subsequent cases.—I am, etc.,

Liverpool. UNA M. WESTELL.

Mitral Systolic Murmurs

SIR,—Dr. William Evans (Jan. 2, p. 8) wisely directs attention to the difficulty of establishing a diagnosis of mitral regurgitation. Everyone may not agree, however, that the term should be abandoned. The traditional teaching that functional incompetence may occur not only in gross left ventricular hypertrophy, as Dr. Evans states, but also as the result of relaxation of the sphincter muscle of the orifice has much evidence to support it. For example, Cowan and Ritchie (*Diseases of the Heart*, 2nd edition, page 291), discussing the symptoms of mitral disease, state: "Incompetence, however, owns one cause which is peculiar to itself. The orifice of the mitral valve is large, while the cusps are relatively small and quite incapable of closing the aperture unless it is narrowed by the contraction of the sphincter muscle. In anaemia and in debility from any cause this sphincter action may fail, and a 'functional' mitral incompetence ensue." Although Sir Thomas Lewis (*Diseases of the Heart*, 3rd edition, page 139) expresses the opinion that a diagnosis of mitral regurgitation has a very limited importance, he states: "It may be useful as an early indication of muscular failure in acute infectious disease and occasionally in old age." With regard to the question of determining whether in a doubtful case blood regurgitates into the auricle during the ventricular systole, it is interesting to note that in 1906 Minkowski obtained characteristic tracings from the left auricle in cases of mitral reflux by passing a stomach tube, capped with a thin rubber bulb, to a distance of 35 to 37 cm. from the teeth, at which point the left auricle is in contact with the oesophagus (Hirschfelder, *Diseases of the Heart and Aorta*, 3rd edition, page 81). I wonder if this method has been employed by other workers.—I am, etc.,

Dundee D. G. MCINTOSH.

SIR,—Though not unmindful of Dr. William Evans's experience as a cardiologist, I welcomed Dr. H. S. Gaskell's letter (March 13, p. 332), and I must include myself among the pigeons referred to by him, and, indeed, I have elsewhere registered a lonely protest against the recent dogmatic tendency to ignore mitral systolic murmurs. The presumption that a systolic murmur which disappears during the inspiratory phase must be innocent is, in my opinion, unsafe and unsound, for the murmur is audible even on full inspiration when the subject is in the knee-elbow position. The audibility of a murmur varies with the proximity of the chest piece to the source of origin of such murmur, and this variation accounts for the waxing and waning of certain murmurs with respiration. Systolic murmurs are abnormal, and it takes more than a simple manœuvre, such as change of posture, to arrive at a decision as to whether a murmur is innocent or not. The subject is of particular interest to me, for, as it happens, by means of a London University grant, I am at present investigating the recruit's heart, and the question of murmurs is of no small concern. If any of your readers should have any views on the subject, I should be glad to include them, with acknowledgment, in a paper which will in due course be published.—I am, etc.,

Solva, Pembrokeshire J. STEPHEN LEWIS, M.D

SIR,—Dr. H. S. Gaskell states that his mind has been completely fogged as a result of reading Dr. William Evans's paper. This is most unfortunate, but surely a fogged state of mind cannot be accepted as an excuse for Dr. Gaskell's failure to quote correctly from the paper in question? Let us analyse and compare Dr. Gaskell's statements and quotations with what was actually written by Dr. Evans in his original paper.

Dr. Gaskell writes: "Again, Dr. Evans states in two consecutive paragraphs in juxtaposition that 'when the murmur is decidedly louder in the upright posture it is the innocent kind'; and then, 'when a systolic mitral murmur becomes louder in the reclining posture the innocent nature of the murmur can be presumed.' In other words, whether it is louder sitting up or lying down it is 'innocent.' Frankly, that does not make sense to me." The latter statement is not surprising. What does make sense, however, are Dr. Evans's own words, correctly quoted: "*In instances in which a trivial* mitral systolic murmur becomes louder in the reclining posture, *and in which a murmur develops at the base of the heart, and particularly in the pulmonary area,* the innocent nature of the murmur can be presumed." The words in italics, ignored or altered by Dr. Gaskell, change entirely the meaning and significance of the paired quotations, besides disproving the charge of contradiction in terms implied by him.

It is Dr. Gaskell who has reached a *reductio ad absurdum* of his own making: in the first place by his failing to grasp the content of what Dr. Evans actually wrote, and, secondly, by drawing conclusions from incorrectly quoted, and therefore misleading, statements.—I am, etc.,

Southend-on-Sea. D. S. LEWES.

War Neuroses

SIR,—Dr. Ronald Fairbairn (March 27, p. 396) says he cannot refrain from raising the question whether the "simple psychotherapy" used in the last war was really psychotherapy at all. Perhaps it wasn't, but it was certainly very successful, as shown both by the immediate results and in the light of a long-term follow-up. In contrast with this the results of the "real" psychotherapy of to-day are disappointing. This is hardly surprising when a modern psychotherapist can make the fantastic suggestion, even if only in a "philosophical aside," that the war neuroses are the result of an attempt to restore essentially "the intra-uterine state of security which was rudely disturbed by the experience of birth."—I am, etc.,

Oxford. ARTHUR HURST.

Treatment of Vomiting after Sulphapyridine

SIR,—Sulphapyridine has a well-known and highly inconvenient toxic effect—severe and persistent vomiting. In all my recent cases of severe vomiting I have adopted the following method of administration. This method has been successful in stopping the vomiting in all cases.

It consists of splitting the 1-gramme (2 tablets) dose, usually given four-hourly, into 1/8 gramme (1/4 tablet) half-hourly, well crushed and dissolved in milk with a pinch of sodium bicarbonate. I start this treatment as soon as it is obvious that severe vomiting is going to persist, and continue it until 10 p.m. With the last dose, I give 1 gramme of sulphapyridine soluble intramuscularly, and then give no more until the following morning at 6 a.m. I then recommence my half-hourly administration. After about twelve hours the dose and interval can usually be increased.

The advantage of this method of administration is obvious as it reduces the necessity for such alternatives as parenteral or rectal administration. It is more convenient, too, than changing to sulphathiazole or sulphadiazine, drugs which are not so often to hand as sulphapyridine. I have mentioned this form of administration to other doctors, and none of them appears to give it this way. It would be interesting to know if a method like this is used by other members of the profession.—I am, etc.,

R. O. GILLHESPY,
Act Squad. Ldr., R.A F V R.

Brow Presentation

SIR,—I was interested to read Dr. G. H. H. Booth's report (March 13, p. 320) of a persistent brow presentation. In March, 1942, I had under my care a similar case. The patient was a primigravida aged 40. On vaginal examination at the 36th week the head was found to be deep in the pelvis in what was taken to be a left occipito-anterior position. At the 39th week she was admitted to hospital with vague labour pains, the membranes having ruptured just before she came in. Sixteen hours later the cervix was fully dilated and the head soon descended to the perineum. After two hours in the second stage there was no advance and the presenting part was noticed to be peculiarly bald. Vaginal examination revealed an anterior brow presentation with the head in the left oblique diameter. Under anaesthesia the head was rotated to the anterior position, and it was then easy to push up the vertex and bring the chin down under the symphysis, thus converting it into a right mento-anterior presentation. Gentle traction with forceps was sufficient to extract a vigorous infant weighing 6 lb. 10 oz. after a small episiotomy had been performed. The caput was not large, but the frontal discoloration was sufficient to convince the most sceptical colleagues on the following morning that the child had, in fact, presented by the brow.—I am, etc.,

Carshalton DOREEN DALEY.

Sulphanilamide in Acute Disseminated Lupus Erythematosus

SIR,—We have been particularly interested in Dr. J. E. G. Pearson's account (Feb. 27, p. 253) of his case of acute disseminated lupus erythematosus which yielded to treatment with sulphanilamide, and would like to bring to his notice our note on the chronic form of the disease (*British Medical Journal*, Nov. 30, 1940, p. 741). All our cases responded to treatment with this drug, and cure was obtained in half the number of cases treated. Our results were so much better than those achieved by other methods in our hands that we have adopted it as our standard line of treatment. It is scarcely necessary to add that prolonged search for a streptococcal focus is made in all cases. One of us (F. G.-H.) has recently successfully treated a case of acute disseminated lupus erythematosus with prontosil by mouth. This case began as the primary acute type.

We would like to add our conviction that lupus erythematosus is streptococcal and not tuberculous in origin, although we have seen both lupus erythematosus and lupus vulgaris occurring in the same patient.—We are, etc.,

Liverpool F. GLYN-HUGHES.
A. M. SPENCE.

Minimum Human Requirements

SIR,—It is a matter for satisfaction that Sir William Beveridge has, in his report, recognized the principle that quantitative standards based on scientific knowledge may, and should, be applied to the measurement of minimum human requirements in food, fuel, light, and clothing. As medical knowledge advances and as cultural demands change, any standards of this nature will be gradually modified, though there can be no doubt that those for food have now been determined with a fair degree of scientific accuracy. We would express our conviction that the food standards now proposed for this country, based as they are on the scales laid down by the British Medical Association, and the League of Nations Technical Commission, accord with the opinion of all accredited scientific workers in this particular field. It is not our business to decide what shall be the actual scales of cash benefit and allowance under any system of social security. That decision rests with the people of this country and with their elected representatives. But we do urge that all such scales shall, in future, be related immediately to the scientifically estimated needs of each type of beneficiary.—We are, etc.,

Venereal Diseases

SIR,—There are doubtless many who will differ from Col. E. A. Chartres (March 13, p. 331), who writes, "This is an entirely medical matter." I attended the conference on Feb. 26 which was addressed by the Archbishop of Canterbury, and was particularly impressed by the remarks of a medical officer of the United States Army who stated that the Church, the medical profession, and the State are all concerned. Col. Chartres may be interested to know what is happening in the county borough of Bournemouth in which he resides. The health committee of the council launched a campaign early in the year before the national scheme was inaugurated. A poster was devised and displayed in various buildings—e.g., factories, works, business premises, public conveniences, social clubs, etc. Cards suitable for each sex were also provided for distribution. These describe in simple language the procedure recommended when a risk has been incurred. The response has been extremely good. I have heard of no unfavourable criticism, but have received requests from individuals and organizations to throw further light on the subject.

Some of the clergy have already followed the lead of the Archbishop, and one vicar especially seemed to strike the right note when he arranged separate meetings for both sexes. At these were discussed, first, the normal functions of the sex organs and the correct moral code, and then venereal diseases. It appears to me that while the Church alone may take a generation or longer to produce an appreciable effect, combined efforts as outlined above are capable of producing rapid results against an enemy already in our midst.—I am, etc.,

H. GORDON SMITH,
Bournemouth Medical Officer of Health

Dietetics of Pregnancy

SIR,—I shall be grateful if you will allow me to make some comments on the correspondence arising out of my letter (Jan. 30, p. 144).

(1) Prof. W. C. W. Nixon is anxious that it should be emphasized that his conclusions apply only to eclamptics. My comments are particularly applicable to this group of patients, since eclamptics are particularly prone to suppression of urine and form the only group of toxaemic patients for which it is known that the mean placental weight is significantly subnormal. Your leader writer's interpretation of Prof. Nixon's conclusions is also rendered correspondingly more erroneous by the restriction of the findings to eclamptics.

(2) Prof. Marrack thinks that I should have taken the trouble to look up American definitions of miscarriage. I have seen two, neither of which agrees with the one he quotes. He also emphasizes the ease of providing extra rations for pregnant women, but neglects the difficulty of providing extra accessory food factors. The necessity for economy has recently enforced the reduction of the concentrations of vitamins A and D in commercial concentrate and synthetic preparations.

(3) Russell and Martin seem to be under the impression that the subject of discussion is Doyne Bell's histogram, which they insist on forcing into a Type I Pearson mould, although the divergences from a normal distribution are no greater

than can be accounted for by sampling errors. They have nothing to say on the fundamental point of difference—the bearing of an arbitrary definition of prematurity on death from immaturity.

(4) The People's League of Health have shown significant decreases in "prematurity" and "toxaemia," as defined by them, to result from supplementing the diet of pregnant women. They have then drawn conclusions concerning the importance of these differences, without providing infant mortality and maternal mortality figures to support the weight they give to these differences, although the committee's terms of reference were to "consider the nutrition of expectant and nursing mothers *in relation to maternal and infant mortality.*" Prof. Young thinks that the conclusions should be accepted without this evidence, because other workers have expressed similar views.

(5) Dr. Yates's speculations concerning the probable reasons for the obscurities in the papers of the Toronto workers are persuasive, in view of their origin, but, of course, they cannot be conclusive. It is clearly unsafe and unwise to base any large conclusions on work which has to be interpreted in terms of "if" and "may have been."—I am, etc.,

Department of Biochemistry, Oxford. R. B. FISHER.

Future of Women in Medicine

SIR,—I have read Dr. Jane Scott Calder's fantastic letter and I cannot allow her remarks to go unchallenged. What does Dr. Calder mean by a "debased feminism"? Are we to bow our heads and meekly accept such few crumbs in the way of medical training and postgraduate opportunities as our male colleagues are pleased to throw to us? If so, then we shall rapidly sink back into the limbo of mid-Victorian obscurity, and we shall have only ourselves to blame. She mentions the "essential dignity" of women. What is this mysterious aura which envelops us like a shroud and constitutes our most precious attribute? Some women can be dignified conducting a delivery in a basement slum; others would be gauche at a State ball; in fact, dignity is not a universal possession, nor is it confined to the female sex. And to maintain that a woman loses what dignity she may possess when she asks for equal opportunities with men to use her intellect and natural gifts is as absurd as it would be disastrous to the well-being of the country at present or to humanity as a whole.

Dr. Calder puts forward certain suggestions for the future education for medical women. She asserts that co-education is dangerous as it leads to laxity of moral behaviour. Nonsense. Coeducation has obtained in all our provincial universities for years, and is universal in many parts of the world, without much obvious decadence among the female population. There is still far too much segregation of the sexes in this country, and the memory of my own schooldays 15 years back makes me blush for shame at the absurd taboos with which we were hedged. Dr. Calder speaks of undesirable heterosexual behaviour; I can assure her that homosexual traits—even the mildest varieties would sometimes appear in a community of women—are just as unpleasant, and far more trying to live with. Secondly, she suggests raising the entrance age to 22 years and wishes to insist on a preliminary 3 years' training as a general nurse. For what? We are training to be doctors, not nurses, and very few people will tolerate 9 years' training for any profession, much less an expensive one such as medicine. She wishes us to train to be doctors to whom the anatomy of the male would be a closed book, in hospitals from which all males down to the smallest babe are rigidly excluded, where the door is closed to the best teachers in the land if they happen to be men, and where we shall finally emerge, after 6 years' seclusion comparable to a nunnery, totally unfitted to earn our daily bread in a competitive world. The mind boggles at the vast field of medicine closed to such an unfortunate being. General practice, public health, industry, are but a few which leap to the mind: no woman could reach specialist rank except in the field of obstetrics and gynaecology—for who is going to send work to a surgeon whose knowledge and activities are confined to the female form?—and even the humble house job would be very hard to find. Men are not likely to enter into this scheme and shut out women patients from their hospitals, so the pendulum will swing still further in their favour, and the woman graduate will, I am afraid, have even more difficulty than at present in finding a niche where she can practise her peculiar profession. There is another point which appears to have escaped Dr. Calder's notice. Where would we be now if women, not only in the medical but in all professions, had not been able to step into the men's shoes and carry on? Dr. Calder objects to contraception, but this practice has come to stay whether we like it or not, and to the vast majority of women who attend birth control clinics it has proved a blessing. The solution to the falling birth rate is not to be found in outlawing pessaries and condoms, but in the provision of family allowances, abolition of the marriage bar in the employment of women—incidentally, our own profession is not guiltless in this respect—and generally making it possible for young people to get married and start families without having to wait years because they cannot afford children.

Dr. Calder wishes to live in a world, professionally at any rate, which consists of nothing but a monstrous regiment of women. She wants to undo all the good work put in by her predecessors, who fought for and eventually obtained a measure of equality, and to put back the clock at least 100 years. She says that she is among those who have "neither the character nor the vocation" for a medical career, yet she has the temerity to outline a system of training for her successors who have both the character and the vocation. It is obvious that Dr. Calder has not the vaguest notion of the outlook of most women doctors, who take a pride in their profession and enjoy working with their male colleagues, and who number many grateful males among their patients.—I am, etc.,

CATHERINE SWANSTON,
Senior Medical Officer, Royal Ordnance Factory.

SIR,—I have read with amazement Dr. J. S. Calder's ideas on the position of women in medicine, and her suggestions for improving their training. None will contest her statement, "Women are created women; men are created men," but there is only one medical profession, which includes a variety of sciences and an ethical tradition built up through the years. I believe the aim of most women taking up medicine is quite simply to have full opportunity to acquire proficiency in that interesting profession, and thereby earn a living in a world that is admittedly and unregrettedly composed of two sexes.

Women are now accepted (sometimes more willingly than at others!) as part of that profession with its privileges and obligations, and I emphatically deny her statement that they are not pulling their weight in it, although I doubt if, without some use of methods that Dr. Calder deplores as "debased feminism," they would ever have had the opportunity. Some have even come through the perils of co-education still possessed of a great interest in the work and some standards of morality and modesty. Some would even gratefully admit to having learnt much of value from the other sex.

Dr. Calder would seem to demand the creation of a new and exclusive profession for women, with a secondary interest in medicine proper, for which the essential qualifications of entrants are: (1) an urge to boom the "nobility and dignity" of woman; (2) a conviction that they are possessed of such qualities and special gifts and inspiration for such a calling; (3) a hypertrophied sex-consciousness necessitating the segregation of the sexes; (4) a private income sufficient to allow a postponement of training till the age of 22 years; (5) agreement with Dr. Calder on birth control. I cannot think such a profession would be overcrowded.—I am, etc.,

Bromley Common. LORNA S. KING.

SIR,—The correspondence begun by Dr. Jane Scott Calder shows that the woman's side of the medical profession still retains its tradition of Victorian idealism. It is, perhaps, time that it came to be looked on as no more than a career which is easily adaptable and well suited to the average intelligent woman who desires to combine a career with a normal family life. A woman doctor's practice can range from that of a normal G.P. to out-and-out specialization, probably and most usefully in gynaecological work.

I was impressed when a locumtenent in districts hitherto exclusively served by men by the number of female patients who had suffered from gynaecological and allied complaints for many years without reporting them. Now, in my own practice, this impression is confirmed. Further, patients are even more willing to ask advice of one who is a wife and mother. It is also inevitable that birth control should take its place. Birth rate is a measure of economic opportunity. Birth control may be assisted scientifically by the medical profession; if not, it assuredly will be by countless folklore methods ably assisted by the advertisers. The normal rate of natural miscarriages is one in every five conceptions. I have every reason to suspect that in this working-class district this is more than doubled. This is largely the result of financial worry. Therefore I consider that satisfactory birth control methods are essential to the prevention of illegal operations and disease. But, excluding the gynaecological aspect, my practice is of normal constitution, with, at present, one-third men patients, both private and panel.

Why should female nurses and not women doctors and medical students be admitted to male and mixed hospitals? On the subject of medical education of women I disagree with Dr. Jane Scott Calder that women should not qualify before the age of 30, as it nullifies her own contention that woman's right is to a home and family of her own, and that she can attain at present at a normal age. The education of medical women should not differ from that of medical men. Few will deny that the majority of medical men become doctors because of its possibilities as a career, and that, on the whole, this produces reasonably satisfactory results. As a graduate of a mixed medical school, my only criticism is that the proportion of women admitted and the opportunities after qualification are not adequate to meet the actual need of the population The moral dangers are chimerical.—I am, etc.,

London. Eleanor Mears.

⁂ Nine of the 25 letters written in reply to Dr. Calder have now been published, and the correspondence is closed —Ed., *B.M.J.*

Case Notes for Salvage

Sir,—Members of the honorary staff of a voluntary hospital here have been shocked to discover that the house committee decided to hand over old case notes and records as a contribution to the salvage campaign, and have fixed twenty years as the period for retention of these notes. This action was taken without consulting the members of the staff who make use of these notes. I cannot believe that the Ministry of Health suggested that such action should be carried out. I should be very glad to know if other hospitals have been affected in a similar fashion. We here feel that the retention of old case notes is a necessary factor in the treatment of cases, and that the handing over of such records is a vital matter not only to the profession but to the community as a whole. —I am, etc.,

Hull. R. Bertram Blair.

Bee-stings, Mosquitoes, and Chloroform

Sir,—I have just read an article on bee-stings by Dr. A. J. Jex-Blake (Aug. 29, p. 241) and other letters in the *Journal* for Sept. and Oct. last. I think perhaps a discovery I made some years ago may be useful in places like Rhodesia where bees are particularly vicious. The discovery, which may or may not be original, is that bees detest chloroform above all things; even a small quantity added to a vapour spray like "flytox" or "flit" (which alone are almost valueless) will cause ordinary bees to depart hurriedly, but for a very persistent swarm it is necessary to add up to one-third chloroform. A very determined swarm of bees once got under the roof of my country cottage; for days they resisted all the usual methods of expulsion, and made themselves a great nuisance by filling the house as well. I then remembered chloroform. After half a dozen puffs with 30% chloroform the angry buzzing ceased, the bees stood not upon the order of their going but went. In less than five minutes the house and roof were clear, and they did not return.

All insects, I find, have similar hatred of chloroform. The very best prophylactic against sandfly and mosquito bites is a mixture of kerosene, oil of eucalyptus, and chloroform in equal parts smeared over the exposed skin. I have used this for some years on fishing expeditions, when camped out in Australia and New Zealand. It will keep bare arms and neck free from sandflies for several hours, and is almost as good as a mosquito net when sprinkled in a tent. Sir Philip Manson-Bahr has recently stated that the mosquito net is the most valuable prophylactic against malaria. I suggest that a chloroform mixture in small individual containers issued to troops in malarial countries would be invaluable, and could be used when a net would be impracticable. A two-ounce bottle lasts many weeks. The incidence of malaria might then be lowered, and the comfort and efficiency of fighting forces enhanced.—I am, etc.,

Wellington, N Z. H. P. Pickerill.

Military Medicine in the Middle East

Sir,—I should like to congratulate Dr. Ernest Bulmer (March 27, p. 374) on his excellent article, which should be carefully studied by all medical officers who are working or who are likely to work in the Middle East. Among the many excellent things in it are his "debunking" of three widely held conceptions. They are: (1) the value of bacteriology in the treatment and management of bacillary dysentery; (2) the value of saline treatment in this disease; (3) the value of the Egyptian climate in chronic chest conditions. From a similar experience in the Middle East I most heartily agree with him on these points.—I am, etc.,

Bristol. Col., R A M.C (T A.) (ret)

Obituary

T. E. HAMMOND, F.R.C.S.

Cardiff will feel the loss of Thomas Edwin Hammond, whose early death has come as a shock to his colleagues. He was a first-class urologist who had been president of the Section of Urology of the Royal Society of Medicine, and his opinion was sought and valued throughout Wales. Within a few weeks the Welsh National Memorial Association has had a dual loss in the deaths, first of Dan Powell, the chief medical officer, and now of the consulting urological surgeon. Tommy Hammond, as he was everywhere known to his friends, did well as a student at Bart's and got his Fellowship of the College of Surgeons a year after he qualified and when still very young. This was in 1913, not long before the outbreak of the last war. He served in Gallipoli as a medical officer in the R.A.M.C., was badly wounded, and probably never recovered from the effects of these wounds. From the time of his discharge from the Army until his death his health had been precarious. He started his surgical work in Cardiff as an assistant in the surgical unit of the Welsh National School of Medicine at the Cardiff Royal Infirmary, and from this appointment became in turn an assistant surgeon and then full surgeon to the Royal Infirmary. He was an attractive teacher, and constantly emphasized the importance of the bodily constitution in its relation to urinary diseases and, in fact, to disease generally. He published several monographs on this theme.

A colleague writes: Hammond had wide intellectual interests and a ready pen, with which he contributed numerous articles to the local press. As a surgeon and a consultant he was thoughtful, thorough, and painstaking. His disposition was to be serious and his personality was pronounced—he had strong likes and dislikes and emphatic views which he did not hesitate to put forward. He served as chairman of the Cardiff Medical Society, and both in its meetings and in those of the Medical Board of the Royal Infirmary was sometimes provocative, but in a way which so often caused mirth to his colleagues that there were no bitter feelings on either side. Tommy Hammond will be much missed both personally and for his work, which was of high standard and served to enhance the prestige of the surgery of the Royal Infirmary.

News of the death on March 24 of Dr. Charlotte Elizabeth Ferguson-Davie (*née* Hull), wife of the Right Rev. Bishop Ferguson-Davie of Fort Hare College, S. Africa, has been received by cable. She was one of the pioneer medical missionaries of the Society for the Propagation of the Gospel, and worked first in India (Delhi and Ranchi) and later in Singapore, after her marriage to the Bishop of Singapore. St. Andrew's Hospital, Singapore, owes its existence to her untiring efforts. The medical mission work under her supervision had been carried on with extreme difficulty in three separate centres in the city, and in buildings quite inadequate for the medical needs of the people. For some years Dr. Ferguson-Davie worked untiringly to collect funds to build a hospital. In 1923 her efforts were crowned with success, and the hospital with accommodation for sixty in-patients was completed and opened. It filled a great need in Singapore, and the medical work quickly developed. Many thousands of women and children were treated annually. In 1927 Dr. Ferguson-Davie retired from Singapore but accompanied her husband to S. Africa, taking an active part in medical missionary work wherever stationed. Her death is a great loss to the medical profession and especially to the cause of medical missions.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on March 13 the following medical and surgical degrees were conferred, all by proxy:

M CHIR —W. M Beattie.
M B., B CHIR.—H. R A Michelmore, B. H. Barns, H. W. Gordon.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examination indicated:

FINAL M.B., CH B.—*Part II*: C. Taylor, S J. van Son

UNIVERSITY OF LEEDS

The following candidates have been approved at the examinations indicated:

M D—J. R Armitage, L. Rosenthal.

FINAL M.B, CH B.—*Part II*: [1] O. Magidson, [2] Isabel H M. Blyth, [2] H. N Burwell, [2] R B. Jones, [2] M Stanton, Jean Bateman, J W. Bishop, J. Bruce, L. S. P. Divers, W D Fletcher, D. Fox, R. Goldberg, J. F. Hanratty, Cecilia Henry, J. D. M. Holt, Agnes A Jervis, Ursula M Kirk, A C. Knight E. R. Lecutier, A L. McKnight, Barbara J Maxwell, M M. Nagley, A. P Percival, H Shaw, Victoria M. D. N Shaw, P. A. Thorpe, Gwenith Turnbull, W N. Wild, J. R. Wilson.

[1] First-class honours. [2] Second-class honours.

The following scholarship and prizes have been awarded:

Infirmary Scholarship, divided between J. A. Holgate and Elizabeth M. Stokes, *Littlewood Prize*, divided between Henriette Lackner, Elizabeth M Stokes, and K. F. Wood. *Scattergood Prize*, O. Magidson. *Hardwick Prize*, divided between R B. Jones and O Magidson *Hillman Prize*, divided between G. M Williamson and Mildred S. Airey. *McGill Prize*, E. R. Lecutier.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Prof. A. J. E. Cave will give a series of Arnott demonstrations and museum lecture-demonstrations, open to advanced students and medical practitioners, at the College (Lincoln's Inn Fields, W.C.) on Tuesdays and Thursdays, April 27 and 29, and May 4, 6, 11, 13, 18, 20, and 25, at 4 p.m.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The following candidates have satisfied the examiners and have been awarded the Diploma of the College: H. Broadbent, W. Calvert, Nora H. C. Clarke, F. B. Davidson, G. S. W. Evans, Jean A. Forbes, Agnes J. M. Gilruth, Irene D. M. Hastilow, Irene E. Howorth, Mary M. Lynch, A. S. Minabbawy, Joyce G. Neil, Erica M. Roberts, Edith Taylor, Mary U. Wilkin.

SOCIETY OF APOTHECARIES OF LONDON

At a meeting of the Court of Assistants held on March 23, with Sir Stanley Woodwark, Master, in the chair, news of the death of the Senior Warden, Dr. F. Gymer Parsons, was received with regret. Dr. J. P. Hedley was re-elected as the Society's representative on the Central Midwives Board. Mr C. Jennings Marshall was nominated Examiner in Surgery in succession to Brig. H. C. Edwards, who has resigned. The Gillson Scholarship in Pathology was re-awarded to Mrs. Helen Payling Wright.

The following candidates have passed in the subjects indicated:

SURGERY.—C P. Brown, J. W. Evans, P. S Hollings, G. L. T. M. Patey, E A Williams, W. H Lillywhite, J Mason, R. Mather.

MEDICINE—J. W. Evans, L. E. D F. Joubert, G. L. T. M. Patey, J. S Pegum, C P. Brown, J M Hanson, P S. Hollings, W. Sommer, C T. Tahil, K. Talboys

MIDWIFERY—J. W Evans, L E. D. F. Joubert. G. L. T. M. Patey, R N. Theakston, C. I. Waters, S Yaffie, A. G. Wolstenholme.

The Diploma of the Society has been granted to J. W. Evans, G. L. T. M. Patey, E. A. Williams, J. M. Hanson, J. Mason, and R. Mather.

The Services

CASUALTIES IN THE MEDICAL SERVICES

Reported Missing, presumed Killed on Active Service.—Surg. Lieut. W. R. B. Dickinson, R.N.V.R.

Wounded.—Major D. W. Bentinck, R.A.M.C., Temp. Major J. G McDowell, R.A.M.C., War Subs. Capt. P. Unwin, R.A.M.C., War Subs. Capt. D. R. P. Wilkie, R.A.M.C.

DEATHS IN THE SERVICES

Colonel WALTER GEORGE PRIDMORE, C.M.G., I.M.S. (ret.), died on March 24 at St. Albans, Herts, aged 78. He was educated at Highgate School and at the Middlesex Hospital and Durham University, and took the M.B., B.S. at the latter After holding resident posts at his hospital he entered the Indian Medical Service in 1891, taking the second place. In the following year he saw active service in the Chin Lushai Expedition in Burma, and later joined the civil medical department of Burma and held important posts as pathologist, and later as ophthalmic surgeon, at the Rangoon General Hospital. In 1911, while in the first of these, he made an important discovery by cultivating for the first time the glanders-like bacillus, named after him, at necropsies on beggars, which is the cause of a rare but fatal disease of Burma and Malaya. In the war of 1914–18 he served as a lieut.-colonel with the Egyptian Expeditionary Force and was mentioned in dispatches. In 1916 he received the C.M.G. and in 1918 he became full colonel, and held an administrative post in India before retiring in 1923. He thus had a distinguished career and showed his versatility in several directions, for he had also played rugby football for both the Middlesex Hospital and Durham University.

Medical Notes in Parliament

Pensions Appeal Tribunals

On March 23, replying to Mr. Arthur Greenwood, Sir WALTER WOMERSLEY said the Government had promised to set up as soon as possible pensions appeal tribunals. He had appointed a subcommittee of his Central Advisory Committee to examine this problem. Thanks to the B.M.A. the Minister now had a list of doctors willing to serve either on tribunals or on tribunal work in the Ministry. It was desirable that the subcommittee should undertake a general review of this list, not with the object of expressing views on the suitability of any individual but to satisfy itself that sufficient doctors of suitable experience could be available without serious effect on other essential war services. In this he had the valuable help of Lord Horder, and he with senior medical officers of the Ministry would review the list and give their general opinion. Sir Walter said he would then call a further meeting of the subcommittee to consider the question in the light of the opinion of Lord Horder and his colleagues. If the subcommittee reported in favour of early establishment of tribunals and the main committee supported that view the Government would review the whole problem. When the Government decided that tribunals could be set up no time would be lost in giving effect to that decision.

A general discussion on war pensions was then opened by Sir IAN FRASER. Mr. R. C. MORRISON said there should be more elasticity in defining the words "due to or aggravated by war service." Hitherto the definition had been a narrow and medical one. When a difficult case came up the Minister referred it to a panel of doctors who were entirely independent. These independent doctors rejected cases without seeing the men at all. It was impossible to convince the appellant or any of his neighbours that a man had been fairly treated when his case had been turned down by doctors who had never seen him. Sir HENRY MORRIS-JONES said it would be no use setting up appeal tribunals unless Sir Walter Womersley had on them men of high academic qualifications who were also men of character and sympathy and able to sift evidence. There would be so many applications that it would be impossible to see all cases individually and some cases would have to be decided on evidence. Sir Henry said that members of the House of Commons got cases by the hundred of men who had been turned down by the Ministry of Pensions as suffering from disabilities not attributable to service. No medical officer in the Ministry of Pensions could say that the disability from which a man suffered would have been contracted had the man remained in civil life, yet cases were turned down on the ground that if the man had not joined the Services he would have contracted the ailment for which he was discharged.

Sir WALTER WOMERSLEY said he would require at least 24 appeal tribunals to cover the United Kingdom, and those who undertook work on them would have to make it a full-time job. It would take them all their time to do eight cases a day if Parliament said the decision should be final and that cases could not be brought to the Minister for review. He wished to pay a tribute to his staff. No one did more than the doctors to try to make the system perfect. The case of the neurotics was difficult. A large number of the Ministry's cases were of neurosis, a question which the medical services of the country would have to face before long because it was increasing. Actually there was less neurosis among the Forces than in civil life. He wished to stress the procedure in connexion with the independent medical experts. It was a certainty that a man would be examined if it were necessary and that he would go before the appeal tribunal personally and have someone with him as an advocate. The independent medical experts had been very effective. They had been appointed by the Presidents of the two Colleges on the understanding that they would be uninfluenced by his Department. Sir Walter agreed that popular opinion was that unless a doctor examined a person thoroughly he did not know anything about the case, but the point at issue with the independent experts was that the doctor had to decide not what was the matter with the man but whether his disability had been caused or aggravated by war service.

Representative Committee of the Profession

Dr. MORGAN inquired on March 25 what medical organizations had been called into consultation on proposals for the future National Health Service, and whether Mr. Brown intended to afford equal facilities to all medical organizations. Mr. BROWN answered that he was consulting a representative group of medical men and women brought together by the B.M.A. with the co-operation of the three Royal Colleges. It was fully understood that views expressed by members of this group at this stage could not be taken as committing the profession as a whole, any more than views expressed by him to the group at this stage represented the final conclusions of the Government. He would be glad also to hear the views of any responsible organization which had bearing on the planning of a comprehensive medical service. He contemplated, a little later on, publishing a statement on the general nature of his proposals so that all concerned—including the profession and particularly its members serving in the armed Forces—had equal opportunity to consider them.

Industrial Health Advisory Committee

Mr. BEVIN said on March 25 that the Industrial Health Research Board was not specifically represented on the newly formed Industrial Health Advisory Committee. A number of members were common to both bodies. Contact would be maintained through these members and through official channels. Duplication of functions would be avoided. The Board was a research body, whereas the committee would not conduct research. It would advise him on technical and scientific problems arising out of the current administration of the Ministry of Labour. Immediately a problem ceased to be a thing which could be dealt with currently and required long research it would be passed on.

Maternal and Infant Mortality

The rates of infant and maternal mortality for England and Wales in 1941 and 1942 were the lowest ever recorded. They were:

	England and Wales	
	1941	1942 (provisional)
Infant deaths per 1,000 live births	59	49
Maternal deaths per 1,000 live and still births		
Post-abortion infection	0.35	0.35
Abortion without sepsis	0.19	0.11
Infection during childbirth and puerperium	0.47	0.42
Other maternal deaths	1.75	1.59

Medical Supplies for China

Mr. RICHARD LAW, replying to Mr. Cocks on March 31, said the British Government had for long been fully aware of the urgent necessity for giving China all possible help in the way of medical relief, and had taken practical steps to do so, both by providing financial assistance and by the dispatch of medical supplies. The Government had made a grant-in-aid of £50,000 to the British Fund for the Relief of Distress in China and a further £41,500 to the Chinese Red Cross. Apart from this, large sums had been collected by voluntary societies in this country, notably the United Aid to China Fund. Every effort had been made to send medical supplies from India, and important allocations—e.g., 5,000,000 tablets of quinine—had been made in the past. At the present time the shortage of medical supplies in India, in addition to the difficulties of transport, constituted serious limiting factors. The Government were fully alive to the needs of the situation and would continue to do all that lay in their power to remedy it.

Medical Advisory Committee.—Mr. Ernest Brown thinks he would not be justified in enlarging the Medical Advisory Committee at this stage by appointing a representative of psychological medicine, but it is contemplated that the committee's membership shall be periodically renewed, and he will bear this suggestion in mind.

Beveridge Report: Consultations with Profession.—Mr. BROWN stated on March 18 that his conversations with the medical profession on the Beveridge report would include discussions with allied professions, such as dentists, opticians, and pharmacists. He would make appropriate arrangements to this end.

Medical Auxiliaries in a National Health Service.—Asked by Sir IAN FRASER on March 24 for an assurance that physiotherapists and masseurs and medical electricians would be consulted through their appropriate organizations on the future of private practices and other relevant matters before any national medical scheme reached its final stage, Mr. BROWN said he intended to hear the views, at the appropriate time, of any representative body whose members' interests were likely to be affected.

Vaccine Lymph.—Mr. VIANT, on March 30, inquired the reason for the change made in the number of live bacteria allowed in vaccine lymph; whether a more potent lymph was needed; and what safeguards were furnished for the protection of the public against the effects of lymph containing such large numbers of living bacteria. Mr. BROWN said the change had been made to facilitate production of vaccine lymph, not to increase its potency. The increase of bacteria mentioned related to harmless adventitious organisms found in lymph as taken from the calf; and the safeguards against harmful micro-organisms remained as stringent as they had always been.

Native Medical Officers for West Africa.—Mr. OLIVER STANLEY stated on March 31 that measures were under constant consideration for increasing opportunities for the employment of Africans as medical officers in West Africa. West Africans had not been formally included in the unified Colonial Medical Service, but 84 African medical officers had already been appointed to the West African Government services. So far, most of the senior medical administrative posts were held by Europeans, but the medical officer of health at Lagos and his assistant were Africans, and a West African held a specialist post in Nigeria. Measures to facilitate the interchangeability of African medical personnel among the four Colonies were being considered.

Diphtheria among Immunized Children.—Among approximately 3,731,000 children immunized against diphtheria under local authority arrangements in England and Wales during the three years 1940, 1941, and 1942, the number of notified cases of the disease was 7,286. The number of immunized children who died from diphtheria during 1942 was 41, as compared with 1,473 deaths among non-immunized children.

Medical News

The Royal Sanitary Institute is holding a meeting at Preston to-day (Saturday, April 10) in the Town Hall. The programme includes a paper at 10.15 a.m. by Dr. J. D. Kershaw on child guidance in its relation to infant welfare.

The London Association of the Medical Women's Federation will discuss some therapeutic uses of endocrines in obstetrics and gynaecology at a meeting in the Hastings Hall, B.M.A. House, Tavistock Square, on Thursday next, April 15, at 5 p.m. Miss Moore-White will contribute a paper on aspects of sterility and treatment, and Dr. Josephine Barnes one on lactation.

A meeting of the Diagnosis Section of the Faculty of Radiologists will be held at 32, Welbeck Street, W., on Saturday, April 17, at 10.30 a.m.

The representatives of the Socialist Medical Association who saw the Minister of Health on March 26 and laid before him that association's views on the organization of a comprehensive health service included Mr. Somerville Hastings, Dr. H. Joules, Mr. Aleck Bourne, Dr. D. Elizabeth Bunbury, Dr. L. T. Hilliard, Dr D. Stark Murray, and Dr. P. Inwald.

A new plasma drying unit which will bring the equipment of the Scottish National Blood Transfusion Association into line with the most modern developments in blood transfusion was opened in the Royal Infirmary, Edinburgh, on March 26 by Mr. Thomas Johnston, M.P., Secretary of State for Scotland.

The Ministry of Health has issued an addendum to Memo. 139/Foods, on laboratory technique for the phosphatase test for heat-treated milk.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* notifications of scarlet fever were up by 253 and whooping-cough by 143; there were 390 fewer notifications of measles.

The only big variations in the local trends of scarlet fever and whooping-cough were those of Yorks West Riding, London, and Middlesex, with rises of 58, 39, and 32 for scarlet fever, and of 36, 53, and 24 for whooping-cough.

Acute pneumonia underwent a general small decline. The only fluctuation of note was an increase of 94 cases in Yorks West Riding, due to a large outbreak in Sheffield C.B.—103 notifications, compared with 9 in the preceding week.

Seven of the 8 cases of paratyphoid occurring during the week were notified in Yorks West Riding, Kirkburton U.D.; 2 cases of typhoid were also notified in this area. Other areas with multiple cases of typhoid were Nottinghamshire, Bingham R.D. 4, and Surrey, Epsom and Ewell M.B. 2.

In *Scotland* measles notifications were up by 109 and those of acute pneumonia down by 100. The increased trend of measles was due to the experience of the cities of Glasgow and Edinburgh, with 89 and 47 more cases respectively. Glasgow, with 90 fewer cases than in the preceding week, was the only area with a decided fall in the incidence of pneumonia. The notifications of diphtheria fell by 19 and scarlet fever by 21; there were 39 more cases of whooping-cough.

In *Northern Ireland* 11 cases of cerebrospinal fever were notified, the largest weekly total during recent months.

Measles

The largest falls during the week were those of Yorks West Riding 277, Gloucestershire 254, Yorks North Riding 222, London 212, Lancashire 190, Durham 123, Devonshire 102. The largest of the increases were recorded in Sussex 208, Essex 162, Staffordshire 121, Denbighshire 96, Somersetshire 92, Cheshire 80, Bedfordshire 73, Monmouthshire 62.

The trends of the local epidemics may roughly be described as decreasing in London and the North but still increasing in the other areas. A comparison of the distribution of the notifications during the past six weeks, in fortnightly groups, illustrates these variations:

Divisions	Number of Notifications during the Weeks			Notifications expressed as Percentages of those in 6–7 Weeks	
	6–7	8–9	10–11	8–9	10–11
London	2,307	2,782	2,516	121	109
South-East ..	3,419	4,089	4,705	120	138
South-West ..	1,174	1,803	2,622	154	223
South Midland ..	4,226	4,663	4,380	110	104
East	1,834	2,482	2,877	135	157
West Midland ..	4,319	5,766	5,634	134	130
North Midland ..	3,098	3,038	2,863	98	92
North-West ..	3,765	3,677	3,582	98	95
Yorkshire	6,426	5,373	4,442	84	69
North	3,069	3,421	3,032	111	99
Wales	1,893	2,186	2,651	115	140

Quarterly Returns for England and Wales

The returns of the Registrar-General for the fourth quarter of 1942 show that the birth rate, at 15.4 per 1,000, was the highest for any fourth quarter since 1930 and was 1.8 above the average of the five preceding fourth quarters. Infant mortality was 48 per 1,000 live births—10 below the average of the ten preceding December quarters and 1 below the low record reached in 1939. Stillbirths formed 33 per 1,000 of the total births registered. The death rate of 11.0 per 1,000 was the same as in the December quarter of 1941, but was 1.3 below the average rate for the five preceding December quarters.

The provisional rates for the whole of 1942 show that the birth rate of 15.8 was the highest recorded since 1931, and the death rate of 11.6 per 1,000 was the lowest since 1930, except for 1938, when it was the same. Infant mortality was 49 per 1,000 live births and was the lowest recorded, being 1 below the previous lowest in 1939. The lowest recorded value was also given by stillbirths—33 per 1,000 live births. The illegitimacy rate among live births was 10 per 1,000 above the average of the preceding five years. The natural increase—excess of births over deaths—was 175,168, or nearly twice the average of 1936-40.

The Week Ending March 27

The notifications of infectious diseases in England and Wales included: scarlet fever 2,185, whooping-cough 1,982, diphtheria 816, measles 19,561, acute pneumonia 1,505, cerebrospinal fever 101, dysentery 92, paratyphoid 1, typhoid 6. In the large towns 73 deaths were attributed to influenza.

No. 11

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 20.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

---

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1.
ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.
Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.
ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.
Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.
Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*
B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Viruses of Varicella and Herpes Zoster

Q.—*Is it established that varicella and herpes zoster have a common virus origin? If so, is it explained why this virus should cause the one disease in the child and the other disease in the middle-aged and elderly?*

A.—The viruses of varicella and herpes zoster "cross-react" in complement-fixation tests and "cross-immunize"; they are therefore either the same or very closely related. The usual result of infection entering by way of the upper air passages is dissemination by the blood stream and hence an attack of varicella. In herpes zoster, on the other hand, there is localization in the central nervous system with spread to the affected area of skin. The causes of this localization are not known, but it is possible that the virus may persist in the C.N.S. following an attack of varicella in early life, to resume activity when resistance to it is depressed by some other cause, either local or general.

Some Sulphonamides

Q.—*What sulphonamide preparations are now in use and for what conditions are they the drug of choice?*

A.—To answer this question fully nothing less would serve than a book, and several on the subject have been published. In the 2nd edition of Wesley W. Spink's *Sulphanilamide and Related Compounds in General Practice,* recently reviewed in this *Journal,* an attempt is made to state in tabular form an order of preference by four sulphonamide compounds for 60 different conditions, and this by no means covers the whole subject. The main indications for the principal compounds may be stated in general terms as follows.

Sulphanilamide.—The earliest (apart from prontosil, which is now no longer used) and until 1938 (again with the same exception) the only sulphonamide compound in general use. Fully effective in infections due to haemolytic streptococci, the gonococcus, the meningococcus, in infections of the urinary tract due to *Bact. coli,* proteus, and other coliform bacilli, and in gas gangrene due to *Cl. welchii.* Has the advantages of great solubility and rapid absorption, universal availability, and cheapness.

Sulphapyridine ("M & B 693").—The main advantage of sulphapyridine over sulphanilamide is that it is effective against the pneumococcus; its introduction in 1938 brought pneumonia within the scope of sulphonamide treatment. Can also be used in any of the conditions for which sulphanilamide is indicated and is preferred for them by some. Recently reported to be greatly superior to sulphanilamide for treating meningitis due to *H. influenzae.* More liable than any other compound to cause nausea and vomiting.

Sulphathiazole.—Chief specific advantage is its greater effect in staphylococcal infections, which are a strong indication for it, although they are unfortunately not as controllable as, for example, streptococcal infections by any form of sulphonamide chemotherapy. Can also be used in any of the conditions aforementioned, and preferred for them by some. Is less toxic than either of the other compounds in the sense that nausea and vomiting and cyanosis are less severe and less common during its use.

Sulphadiazine.—Full data do not yet exist for assessing the relative efficiency of this drug in various susceptible infections, but it appears to have the same scope of activity as its predecessors, and its efficiency is fully proved in pneumonia. Has the great advantage of almost complete freedom from subjective toxic effects. Very costly and at present very difficult to get.

Sulphaguanidine.—Poorly absorbed and therefore mainly retained in the bowel; sole indications for its use are intestinal infections, particularly bacillary dysentery. Succinyl sulphathiazole is also recommended for this purpose and for disinfecting the colon before operations on it.

In addition to these compounds, there are soluble derivatives for administration by injection and others with more restricted uses. It is unjustifiable to dogmatize about the relative merits of the first three for many purposes: acute streptococcal infections and cerebrospinal fever, for instance, respond well to all, and there can be little to choose between them. Generally speaking, sulphonamide chemotherapy is more successful in acute than chronic infections, and if it is indicated at all it demands adequate dosage, usually not less than 1 g. of the drug four-hourly for an adult. It is futile and may actually do harm to give only a 1/2-g. tablet t.d.s., and useless in most cases to continue treatment for more than a week if no effect has been obtained.

Psychological Impotence

Q.—*I should be glad to know if any effective treatment is available for a case of psychological impotence in a man about 45 years who complains of tiredness, lack of energy, etc. I have tried injections of testosterone, 10 mg. weekly, benzedrine tablets, etc., but with no result.*

A.—The treatment of a case of psychological impotence is psychological, and but little help can be expected from benzedrine or from any other drug if the psychological factors have not been dealt with. Sometimes these factors are obvious and can be eliminated by reassurance, encouragement, and suggestion. At other times they are the result of some deep-seated conflict which can be discovered and satisfactorily treated only by an expert psychologist. This being the case I would suggest that this patient be referred to a competent psychotherapist.

LETTERS, NOTES, ETC.

Liq. Ferri Perchlor. for Sore Throat

Dr. N. Corbet Fletcher (London, N.W.3) writes: The note by Dr. Ralph Jones (March 13, p. 340) on the administration of liq. ferri perchlor. for sore throats interested me because my father taught me to use it in combination with pulv. potass. chlorat., and, further, to instruct my patients to gargle well before swallowing each dose. Rarely have I known this mixture to fail in my 40 years of general practice. But perhaps the best comment is the fact that many patients who have once tested the mixture return and ask for a bottle of "gargle and swallow."

Mr. J. Cole Marshall, F.R.C.S. (London, W.1) writes: I was very pleased to see the letter from Dr. Ralph Jones (March 13, p. 340), and should like to give my experience of the efficacy of liq. ferri perchlor. Some years ago I had a very nasty-looking tonsillitis. I consulted my friend, Dr. Alex Gavin, and he thought I had diphtheria, and took a swab. In the meantime he ordered me 30 minims of liq. ferri perchlor. taken in half a tumbler of soda water every four hours, and I also painted my throat with Mandl's paint. In 24 hours my throat was nearly clear—the swab showed a heavy growth of haemolytic streptococci. A year or two later I got an acute attack of erysipelas in my right leg from a crack between my toes. My leg was scarlet from the ankle to the knee, and my temperature was 103.5° F. I immediately took large doses of liq. ferri perchlor. in soda water and applied glycerin and belladonna to my leg. In two days my leg cleared up and within a week or less I was convalescent I always feel that it is a pity that this old remedy is not more widely used.

Temperature-taking in Tuberculosis

Dr. P. C. Matthew (St. Ives, Cornwall) writes: You state (March 6, p. 308), in answer to a correspondent's query on temperature-taking in pulmonary tuberculosis, ". . . for a half-minute thermometer it is immaterial whether the time chosen is 2 minutes or 5 minutes." This raises a point that has interested me since 1937, when I stayed for a time at Montana Hall, in Switzerland. I noticed there that Dr. Hilary Roche insisted upon 10-minute mouth readings, and he told me that only this gave a degree of accuracy equal to rectal readings. Why does a half-minute thermometer take up to 10 minutes under the tongue to reach body temperature? The answer I think is that the mouth must be closed for 10 minutes before the "under-tongue" temperature equals body heat. Anyone can try this by taking 2-, 5-, and 10-minute readings under the tongue after (*a*) breathing through the mouth, and (*b*) sitting with the mouth closed. The rise to normal in the first case is gradual; in the second rapid. This 10-minute technique is uncalled for in dealing with the ordinary fevers of general practice, but is invaluable in detecting unsuspected temperatures of 99–99.4° F.

Corrigendum

The last sentence of Mr. P. B. Roth's letter on surgery of tendons (April 3, p. 426) should read: "I should very much like to know what results are obtained by others who have a large experience of tendon suture."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY APRIL 17 1943

STRATEGY AND TACTICS IN RESEARCH*

BY

F. M. R. WALSHE, M.D., F.R.C.P.

Physician in Charge of the Neurological Department, University College Hospital

Of the various fields of medical activity now coming under review in the discussions being held on the future of medicine in this country, that of research must command its full share of attention. If the greatest possible advancement of knowledge is to be secured, those in whose hands the reorganization of medicine will lie need a sound conception of all that is embodied in the idea and in the execution of research. We may not assume that everyone eager to provide us with a bright new medical world has the experience or insight necessary to deal with the problems of medical research, nor even that all of those actually engaged in it are endowed with the clearest vision on the subject. Some familiarity with the literature in which original investigations in my own field of medicine are recorded, various discussions that I have listened to, and schemes of research upon particular problems that I have known propounded have led me to believe that not a few of those who engage in research work, or who find themselves—often for quite irrelevant reasons—in a position to initiate and control it, have extremely limited views as to what constitutes good research, how to plan and set about it, or how to interpret and use to the best advantage the results it yields. The present time therefore seems apt for an attempt to formulate some general principles of a strategy and tactics of research. I shall concern myself principally with medical research, but my remarks may possibly have a wider application if they are well founded.

Research in the Past

Until comparatively recent times medical research has been pursued largely in the voluntary hospitals and their medical schools. Most of those from whose ranks the original workers were mainly recruited—namely, the honorary medical staffs—have from the nature of the voluntary hospital system been compelled to gain their livelihood by the private practice of medicine. As a result clinical research has been hampered in its full development, for those engaged in it have found themselves increasingly drawn away by the demands of practice, until in middle life most of them are compelled to relinquish all hope of serious original work. Even under conditions so adverse, their achievements in the past have been considerable, and have provided the foundations upon which a more fortunately placed younger generation may now build. Perhaps not all of this generation realize fully that some at least of the broad perspectives now opening before them they enjoy because they are, as it were, standing on the shoulders of their unsubsidized predecessors. Some of them, it may fairly be urged, are inclined to scorn the base degrees by which they did ascend, and therefore a tribute to the labours of past generations in advancing medical knowledge is not wholly superfluous.

Yet under these past-time conditions advance was uncertain and somewhat fortuitous, and none will deny that the increasing pace of scientific work requires that greater opportunities for clinical research should be provided. The growing complexity of the problems before us, and of the research methods essential to tackling them, makes greater demands upon the individual than in the old days when the hewing out of the rough features of medical knowledge by relatively simple methods was possible for men who, in more leisurely times, were also engaged in the practice of medicine and surgery. Research is becoming increasingly a matter of ever finer analysis of fundamental bodily processes by technical methods of great complexity, and is too exacting a mistress to be satisfied with less than the first claim on the worker's endeavour.

Despite the steady increase of opportunities for the free pursuit of clinical science that the past 20 years has provided, further opportunities must be forthcoming if British medicine is to regain its position in the van of progress. It is not my prime purpose to discuss how far simple organization can achieve this result. Of organizers we need fear no dearth, nor of those ready to place all their hopes in planning and to cherish the most sanguine expectations as to what can be achieved by committees. My first concern is to consider the part that must be played by those who do the research work if this is to yield a good harvest.

One of the outstanding features of medical research of the past is that for the most part only the man with the urge to explore the unknown engaged in it. He could hope for no material reward from doing so. Indeed, he might easily suffer from his preoccupation with original investigation. It offered him no prospect of a career; what we may call the professional researcher in established laboratories was apt to look askance at him as an amateur, nor could he expect to join the select ranks of press-famous doctors by devoting himself to it. In fact, he too often ended as one of those pathetic figures of whom we used to see it stated in obituary notices in our medical press that "he did not attain that success in practice that his merits entitled him to, but his colleagues appreciated his worth."

Only the rare man who combined insatiable scientific curiosity with abounding vitality and enthusiasm could succeed in both research and practice. Victor Horsley was such a man, but we cannot tell when we may look upon his like again. Hughlings Jackson, to take an outstanding example of the original thinker in medicine, thought long and profoundly on the problems of neurology and psychology and greatly enriched knowledge because it was in him to do so and would not be denied. It is as difficult to believe that any formal organization of research in his day would have made him more productive as it is to suppose that English poetry would be any more rich and lovely than it is had all poets in the past been given salaried posts and relieved of financial difficulties: a thought that we may well ponder when thinking of the possibilities of mere planning for achievement in the realms of the mind.

---

* Being a paper read before the Society of British Neurological Surgeons on Aug. 1, 1942.

The subsidizing of medical research has grown and will continue to grow, and thus many now engage in it, and will in future do so, who, in days gone by would have been neither willing nor able. Their compelling motives are many and various. As always, a few have the true vocation and eagerly embrace the enhanced opportunities now opening before them. Many enter research for more pedestrian reasons: some because it offers a safe refuge from the exhausting labours, responsibilities, competition, and financial uncertainties of private practice; others because it affords them the illusion of an intellectually higher life; a few, perhaps, because they are misanthropes who, in the laboratory, can hope to escape contact with their kind; some just choose it upon a dispassionate calculation between the various openings a medical training offers them; and some, alas, merely as a stepping-stone to more attractive adventures in other fields of medical activity.

The True Discoverer

Whatever their reasons, a growing army of men and women are enlisting in the ranks of original investigators. Of all these, however, we can look for very few in the first ranks of true discoverers: those who infuse their technical competence with scientific imagination, who see their problem in essence before they proceed to tackle it; who know how to ask the experimental questions best calculated to elicit from Nature the relevant answers; who not only add new facts to store but see their significance and can embody them in the ordered knowledge that is science. Not content merely to dig for gold, they also refine it, knowing that it is useless until they have done this, and that isolated pieces of information are merely the raw material of knowledge. A capacity for the unresting contemplation of the facts of observation is their surest and peculiar weapon and their guide in experimental work. They are the strategists of research.

No planning can provide us with these men or determine the goal of their labours. When they possess the added gift of being able to attract younger men around them their powers of discovery are immeasurably enhanced; for they can train their successors, and can direct the labours of workers of lesser rank, the tacticians of research who when a problem is formulated can devise a means of tackling it. Under them also work the third rank of research workers, to whom can be confided limited and precisely defined tasks in the larger plan of campaign.

Here we have a sort of spontaneously arising organization that has grown round a personality and has owed little or nothing to deliberate planning. When this comes into existence it is the richest of all sources of original knowledge. Within our own time and in this country, physiology, biochemistry, and clinical science have given us brilliant examples of such schools under the leadership of Sherrington, Gowland Hopkins, and Thomas Lewis. Woollard, had he lived long enough, might have established such a school in anatomy. Given such leaders, research of the first order will flourish, however scanty the material resources available, however negligible the organization from without. Going further afield, we have a striking illustration of this in the school of Magnus of Utrecht, a true offshoot of the Sherrington school of physiology. Over a period of years a sequence of closely related investigations upon the physiology of body posture came from this active centre of research, and was recorded in a series of papers that were a model of what such records should be: concise, crystal-clear in language, and with step following logical step in the presentation of facts and argument. All this work was carried out in a cramped and ancient building, once a plague hospital, as ill adapted for modern research as may be imagined and as poorly endowed. Yet the personality of the leader inspired a band of paid and voluntary workers—de Kleyn, a practising surgeon, being one of the latter—to complete one of the most fascinating chapters in the records of neurophysiology. In short, it is round the man and not round the plan that the wheels of research revolve most rapidly.

All this is not to deprecate some attempt to organize our resources, but rather to indicate the limits of what planning and research foundations can achieve. Geniuses for research are not created by committees; they are not even invariably recognized by them in time to afford them support. By the time Magnus at Utrecht could look upon a new and fully equipped laboratory his last experiment had been made.

Lines of Approach in Strategy and Tactics

These considerations bring me back to my starting-point—namely, the great importance of sound ideas as to a strategy and tactics of research if the greatest efficiency is to be attained. Perhaps some apology is called for from me at this juncture. It may be thought that only one whose active life has been spent in research can be competent to discuss this question. Up to a point this is probably true, yet, after all, the onlooker sees a great deal of the game, and it is as an interested spectator of the fields of neurophysiological and clinical neurological research during the past quarter of a century, and for part of that time associated with the editorship of *Brain*, that I venture to give my impressions of the quality of strategy and tactics to be seen in these fields of medical and allied research.

Claiming no more than this, then, I submit that a sound research strategy connotes a familiarity with what has already been accomplished in the field of investigation to be explored; but it calls for more than this—namely, for a clear grasp of the implications of earlier work and some discernment as to where it is probably leading. Some pattern has to be sought in the numerous and often seemingly unconnected items of information available, and the gaps in this have to be recognized as the field of knowledge is critically surveyed, since from this recognition it may be hoped to get a lead as to what questions remain to be answered before the complete pattern of the bodily function or process under inquiry can be revealed. The strategist's scientific imagination will show him what lines of approach offer the best hopes of success, and when to abandon any given line and start afresh. He may have, and must be able, to recast his ideas completely regarding the nature of his problem should unlooked-for results make this necessary. This in turn requires that he shall have the intellectual integrity and clarity to sacrifice his provisional hypotheses to the facts if these demand it. Experience shows that this dilemma is not always successfully solved by the research worker; for his hypothesis may have become dearer to him than the facts, which he then proceeds to tidy up in conformity with his preconceived notions, turning a blind eye to one and "modifying" another. By tactics of research I have in mind the drawing up of a precise experimental plan, once the general intention of the research has been thought out and formulated. It implies the devising of experiments—that is, of questions designed to extract the answers from Nature. In doing this the worker shows his capacity for cross-examining Nature and his purpose in doing so. His experiments, therefore, are not well-intentioned gropings in the dark but skilfully directed probings. Some there are who, while not being strategists of the first order, are adept in this tactical planning once the purpose of an investigation has been defined for them. Now, in the world of scientific activity as we find it there are not enough strategists of the first rank to go round, and thus it comes that many investigations are carried through with no longer view than the acquisition of some piece of information as an end in itself without any clear thought as to its possible implications. Once gained, this piece of information is put on record, but its orientation in the larger field of related knowledge and its building up into a general body of thought seem beyond the vision of the workers. Indeed, we sometimes ask ourselves what was in their minds in undertaking it. They have, as it were, rooted up industriously a sort of scientific truffle and have then promptly lost interest in it. The journals are full of these bits of isolated work, of which it may be said that they are no more than the raw material of knowledge. Not a few workers pass their active lives going from investigation to unrelated investigation on no discernible plan, never pausing to contemplate the full implications of their work, but, with an unresting haste and an apparent horror of contemplation, proceed on their mission as collectors of information. Sometimes one cannot but suspect that they cherish the illusion that he who publishes four papers is a better man than he who produces but one, and there is not a little in the current standards of values concerning these things that encourages them in this dreadful notion. Concerning these standards and the question of the productivity of the research worker I shall have something more to say later.

Now, the research worker of the first rank does not leave his facts of observation lying on the grass in this unfinished state, nor does he collect facts just for the sake of doing so. He extracts the last grain of significance from his observations before he leaves them to pass on to a logical next step in his planned campaign of investigation. It is true, of course, that the raw material of less polished labours may from time to time provide him with essential links in some chain of evidence or, illuminated by his thought, may come to have crucial importance. Yet this is no justification for research work as lacking in purpose as in method. At the other extreme we find scanty or ill-substantiated observations made the foundation of some elaborate structure of hypothesis which they cannot support. To this variety, also, the literature of research is no stranger.

Shortcomings in Research

But perhaps the most pitiful travesty of original investigation is that undertaken for some irrelevant reason, such, for example, as that research work gives a committee, an institution, or a hospital a good name, and creates an atmosphere of scientific glamour highly gratifying to those promoting it or engaged in it. An apt variety of this aimless activity was the scheme I once heard proposed to take polygraph tracings from all the patients admitted to a certain institution over a twelve-months period, on the naïve expectation that "something's bound to emerge!" No one paused to ask what might be expected to emerge, or how, once emerged, it was to be recognized as a significant phenomenon.

Not less unpromising were the labours of a committee within whose terms of reference it was to initiate and support schemes of research, when it met to think out from the inner consciousness of its component members things to research about, much as one might ask at a children's party, "What shall we do next?" Closely related to this conception of research is the notion that all that is needed is an elaborate questionary for a collection of assorted workers of unknown capacity to conform to and to fill in, some statistical amateur then to distil knowledge from the completed returns. From this Gallup poll to research by automatic calculating machines seems but a brief step, for the use of the intellect has been virtually done away with.

But lack of imagination is not the only shortcoming of much modern medical—and other—research. A not less pervasive evil is the tendency to accept statements of fact, and even hypotheses, on trust, more especially when they emanate from writers to whose name prestige attaches. Prestige, indeed, may be a deadly peril in scientific thought. Every statement and every hypothesis on record must stand or fall on its merits, irrespective of its author. Nothing is more common than to read in the opening paragraphs of an original paper the phrase, "So-and-so has shown that," when more often than not "So-and-so" has shown nothing of the kind—he has only said or suggested it but has not demonstrated it. Once thus referred to, a false air of reality attaches to the statement and it passes insensibly into the category of things we accept as proved, where as likely as not it does not belong. In this way a hypothesis with no demonstrable validity may obtain a measure of acceptance and a lease of life to which its merits by no means entitle it—and it may even hold up fresh thought for a generation by its malign influence. Yet really critical examination would have revealed from the outset that it was fallacious or unsubstantiated. That this should be so is a reproach, and suggests that what I have spoken of as the unresting contemplation of the facts of observation does not engage original workers to the degree it should.

Necessity for Critical Analysis

This brings me to the role of critical thought in the field of research. This, and this only, can keep the world of original thought alive and fresh, can sort the wheat of sound hypothesis from the tares of rash and ill-thought-out speculation, the ephemeral from the lasting. When one considers the flood of papers dealing with new observations—or rediscoveries of old observations—that surges about us in a rising tide each year, it is clear that the imperative necessity for quite ruthless critical analysis becomes even greater. Yet who wants to shoulder this role of intellectual inquisitor? No one, indeed, with any regard for his own advancement or peace of mind. It has become the craven fashion to decry critical analysis by attaching to it the unpopular name of "destructive criticism." Yet we must clear the ground of the lumber of unreliable observations and unsupported hypotheses before advance is possible. Those of you who have read—as we all should read—Trotter's *Collected Addresses* will find in them the following passage, which cannot be too constantly borne in mind. He says: "The common tendency to regard destructive criticism as always easy and generally reprehensible is one I do not share; I doubt if it could be acquiesced in by any sensible person making a frank survey of the intellectual world to-day. At no time in the history of the intellect has the sanitary work of destructive criticism been more needful." If for the words "intellectual" and "intellect" we substitute "medical" and "medicine," these words lose none of their force. Yet if there is nothing the research worker needs more as a stimulus and a guide, there are few things he dislikes more than critical thought applied to his labours. He is always able to persuade himself that any criticism is inept, unnecessary, or impolitic. This, I suppose, will always be so—for the investigator is as full of human frailties as the rest of us; yet this emotional reaction makes all but the most hardy shrink from those periodical and candid surveys of the field of knowledge the lack of which may allow the most fallacious of generalizations to dominate thought for a generation.

Yet it is of the very essence of scientific advance that we should have criticism and synthesis as well as observation. The situation is well summed up by Arnold Toynbee, in respect of history, in the introductory chapter of his *Study of History*. He says: "The three conditions of criticism, transitoriness, and succession under which the scholar has to do his work . . . are conditions that arise from the nature of scholarship itself, which makes its progress by a rhythmic alteration between two activities—the collection of materials and their arrangement, the finding of facts and their interpretation—just as a physical organism lives and grows by an alternating between eating and digestion. The old fable of the belly and its members points the moral that neither activity is superior or inferior, prior or posterior, primary or parasitic, but that each is inseparable from the other as a part of the same whole, and complementary to the other as a phase in the same recurrent process. For the alternation perpetually recurs in virtue of the very nature of thought. When the mind is employed in finding facts, its sheer success inhibits it sooner or later from fact-finding uninterruptedly and *ad infinitum*. Sooner or later it finds itself so formidably beleaguered by the mass of facts which it has gathered round it that, until it has sorted them out and arranged them in some kind of order, it can no longer sally out into the Universe to gather more. Then the mind changes its activity perforce and employs itself for a season in making syntheses and interpretations."

The season of synthesis and interpretation is long overdue in medical science. We have more facts than we can digest—facts enough, indeed, to make salutary advances in ordered knowledge were we given the time and encouragement to make them. Yet the present climate of opinion is adverse to contemplation and the exercise of critical thought, and cries loudly and unthinkingly for ever more facts: the normal rhythm of thought is suspended and we sit bewildered amid the chaos of facts we are not encouraged to put in order.

There is another point about medical research that seems to require a brief reference, and that is the notion, most tenaciously held by those who know least about clinical work, that good research necessarily means work in the laboratory and experiments on animals. This is a crude fallacy; the medical research worker should be the master of all methods necessary to his problems, and the slave of none. He must be ready to extract from each method what it offers, and to choose the combination of methods essential to the successful prosecution of his task. Knowledge will not be advanced by creating a false antithesis between observation at the bedside and the study of the human subject by whatever means are legitimate and useful, on the one hand, and work in the laboratory and on animals on the other. The observation of human disease has by no means exhausted its resources, and even simple clinical observation may yet provide valuable and essential lines of attack on problems of disease, that cannot perhaps be solved without the additional aid of the laboratory and animal experiment. I cannot believe that any medical research worker can afford to divorce himself from clinical studies. When he does so he invariably loses touch with reality.

External Dangers

If the shortcomings of much medical research that I have indicated really obtain, they are such as can be remedied only by those engaged in that research. Yet there are external dangers that increasingly surround research as it becomes progressively more organized from without by controlling bodies whose paid workers the researchers are. I have ventured to suggest that many more such workers are ready to make observations or experiments than appreciate the necessity for continued thought about their work and its implications. This tendency is not checked when research organizations expect their workers to manifest productivity in terms of published papers. The man who has every year to draw up his annual report showing what he has accomplished can scarcely be blamed if he does not spend much time in contemplation. He will not care to report that he has as yet published nothing, is not ready to publish anything, and has not got very much further than surveying his problem.

Some sacrifices of independence and freedom have to be made when research is widely organized and research workers are paid salaries. Even research foundations have to satisfy their "public" that they are getting results; they have to do some window-dressing. Only an informed and enlightened control can secure for the research worker that freedom from which alone his best work can flow. He must have time to think, and be encouraged to do so, and he must not be haunted by the fear that his productivity is being measured in terms of papers or that his share of the organization's financial resources is grudged him. Under the experienced and sympathetic administration of the more important research foundations he is least likely to suffer in this way, but if and when the State or public bodies—through hospital and other services—take a hand in the matter, and if considerations of political expediency begin to appear, the salaried research worker may end by becoming a kind of scientific helot from whom quick results, in directions not always determined by him, are looked for. Now is the time to safeguard him from this melancholy fate.

One last danger should, it seems to me, be foreseen in the organization of medical research in the new order—namely, the danger that the worker in pure research may be segregated in central institutes remote from hospitals and medical schools. I believe this would be fatal to true progress in medicine. It would take the spirit and the inspiration of inquiry from the schools, wherein alone are to be found the recruits to the ranks of original investigators. It would deprive the student of contact with the research worker, and would deaden the quality of the endeavour of everyone concerned in hospital work and medical teaching. The research worker himself would suffer no less from this isolation from the world of medical endeavour, from the true battle-front of medicine. Thus isolated he would soon lose his sense of reality and of proportion. He would cease to have the necessary vivid awareness of the nature and difficulties of medical problems. It has commonly been so in the past.

Conclusion

It is idle to look back, but how enviable in retrospect was the lot of the physician or surgeon of a past generation who engaged in research work to satisfy his own scientific curiosity! He could think at his leisure, could publish his results when these were ripe and at his chosen moment: he was not harassed by the thought that something was expected from him at stated intervals in the calendar, or by the fear that some organization would begin to think that he was not worth his keep as a research worker. It may be true that we can no longer leave the matter of medical research to his amateur care; but will the subsidized research worker, caught up in the machine of organized research, ever savour the true taste of discovery so fully? It is hard to believe that the human contacts the older workers made in the practice of medicine were not at least one source of their inspiration, or that the time they gave to the treatment of the sick was really the waste some modern advocates of reform would have us think. Therefore, while fully recognizing that the times before us demand a more organized research effort than we have had hitherto, we may yet regret the probability that something of what was most favourable to the best work may be lost in the process, and we may hope that those who are reorganizing the fabric of British medicine will bear all this in mind and will make the conditions under which the salaried research worker has to labour and live most favourable to the free and unhampered development of his powers.

THE PATHOLOGY OF CLOSED INJURIES OF THE CHEST*

BY

J. V. WILSON, M.D.

Major, R.A.M.C.; D.A.D.P. of a Command

After two years of continuous war work I shall here attempt to review in broad detail some experiences gained in the routine post-mortem examination of battle casualties, selecting for special analysis thoracic injuries of the closed type. My material has been drawn from both Service and civilian casualties, and it can be claimed to be wide and varied.

By a closed injury to the chest I mean either that the skin and subcutaneous tissue were intact or that, if these were pierced, the course of the missile had been such as to leave the pleura intact and so the pleural space had no contact with the outside air. This study excludes all cases in which a foreign body had entered the pleura or thoracic viscera, and deals with a group of cases that, to my mind, are the most interesting and in some ways the most important of war injuries. The cases may be divided into two main categories—those due to direct violence to the chest and those in which the injury to the thoracic viscera is indirect—i.e., a result of injury elsewhere in the body. Fat embolism is an example of this latter group: here the lung changes are very definite, but are usually the result of injury elsewhere, such as fracture of long bones. The former group includes: (*a*) lacerations, (*b*) contusions, (*c*) blast injuries (pulmonary concussion); it is principally with these cases that I shall deal.

Lacerations

Laceration of the heart or great vessels is of little pathological interest. It rarely if ever occurs in closed chest injuries, and when it results in rupture is rapidly fatal. A case of ruptured aorta due to blast has recently been reported by Wilson and Tunbridge, but I have not seen any further case of laceration of heart or large vessels in my series of war injuries. Laceration of the lung, on the other hand, is of great importance, and has occurred in this series with considerable frequency.

Case 1.—A gunner aged 28 was admitted suffering from shock and complaining of pain in the right chest. A bomb had exploded near his gun position and he had been thrown up against part of the gun. It was not clear whether he had been actually struck by a bomb splinter: the only evidence of external violence was a cut on the forehead about 2 in. long just to the right of the midline and extending upwards from the root of the nose. He was tender all over his right chest and blood was present in the right pleural cavity. Radiographs revealed multiple fractures of the ribs and a large right-sided pleural effusion. He died about six hours after admission.

At the post-mortem examination there was no evidence of external injury to the chest. The 3rd to 10th ribs on the right side were fractured just beyond the neck, while the 6th, 7th, and 8th ribs were also fractured in the mid-axillary line. The right pleural space contained about 1,000 c.cm. of fluid blood and a small blood clot. The right lung was lacerated by the fractured ribs along the line of the angle of the ribs; there were multiple areas of haemorrhage all over its substance, and it was partially collapsed, a deposit of fibrin being present on the diaphragmatic surface and the lower half of the lower lobe. The left pleural space was intact but contained a small excess of serous fluid, the lung itself being congested but with no definite localized areas of haemorrhage. The gunner had been standing about 40 yards away when the bomb exploded, and most of his injuries would appear to have been due to direct violence, either from a flat bomb splinter or from being thrown against a solid object.

---

* The opening address at a B.M.A. meeting (Over-seas Branch), April 30, 1942.

Case 2.—An officer was working with a party of men on an aerodrome when a bomb exploded 150 ft. away. He was hit on the right side by a flat piece of bomb splinter and thrown to the ground. There were no external injuries except bruising of the right upper arm and right chest wall. On admission he was shocked and collapsed, and died about an hour later.

Necropsy revealed no external injury to the chest wall, but there was considerable bruising of and haemorrhage into the muscles of the right chest wall, especially posteriorly. The 4th, 5th, and 6th ribs had been fractured posteriorly along the angle of the ribs and again in the anterior axillary line. They had been driven in, rupturing the parietal pleura and intercostal vessels. The right pleural space contained a small amount of air and 4,000 c.cm. of fluid blood—i.e., a pneumohaemothorax had developed. There was no collapse of the right lung, but the mediastinum had been pushed across to the left side. The right lung was the seat of a large haemorrhage which involved the lower half of the upper lobe, the middle and lower lobes except their anterior margin, and extended throughout the substance of the lung. Three large subpleural bullae were present—one on the anterior aspect of the lower part of the upper lobe, one in the interlobar surface of the middle lobe, and a third, which had ruptured, on the posterior aspect of the lower lobe. This lung had been torn superficially on the posterior aspect opposite the angles of the broken 4th, 5th, and 6th ribs. The left lung was congested throughout and there was a haemorrhagic area in the posterior portion of the lower lobe, involving the deeper portions as well as the subpleural area.

These cases illustrate the chief features of lung laceration in closed chest injuries, and it will be realized that their seriousness depends not so much on the actual lung injury as on the development of complications. Laceration of the lung is rarely severe and seldom causes death in itself: a haematoma forms round the actual tear, but, owing to collapse of the lung tissue, haemorrhage soon stops. The neighbouring lung shows congestion, but there is seldom any evidence of gangrene of the torn edges, since the blood supply is so generous.

Complications

The complications which occur and which may prove so dangerous may be grouped as follows: (1) pneumohaemothorax; (2) compression or collapse of lung; (3) infection.

1. *Pneumohaemothorax.*—The degree of pneumothorax present is as a rule very slight. The clot which forms usually seals off the alveoli, and collapse of the surrounding lung helps this process, so that the amount of escaping air is small and would appear to be quickly absorbed. Subpleural bullae are rarely extensive and seldom rupture. It is true that the nature of the lung injury may be such that a valve may be formed and in this way a tension pneumothorax may develop, but in my experience this is extremely rare. Haemothorax, on the other hand, is common, and may be very extensive. There are two possible sources of origin for blood in the pleural space; it may result from:

> (*a*) Bleeding from the intercostal and mammary vessels, which, being systemic, may be very profuse and difficult to stop. (*b*) Bleeding from the pulmonary vessels at the site of laceration. This is rarely severe or fatal in itself. The pressure in the pulmonary vessels is low, the mean arterial pressure in the pulmonary circuit being about one-sixth that of the mean arterial pressure in the aorta, while the pressure in the pulmonary veins is near the zero level. The surrounding lung tends to collapse and the diaphragm on the injured side rises, so that Nature can in most cases be left to deal with this type of bleeding.

The differentiation of these two varieties of injury is important from the point of view of lung surgery.

The pleura is a mesothelial structure and reacts to haemorrhage as if it were a foreign body—i.e., with a mild inflammatory type of reaction. Locally there is an outpouring into the pleural space of a fluid rich in protein, accompanied by fever that is constant and without any evidence of toxaemia and so differs from the swinging temperature in the toxic patient with empyema. The local exudate of fluid not only increases the volume of the haemothorax present but may also cause a mild dehydration, which must be considered in treatment. Its presence and extent can be gauged fairly accurately by comparing the haemoglobin content of the pleural fluid with that of the patient's blood. An interesting fact about haemothorax is that the blood seldom clots to any great extent. A small clot may be present, but the bulk of the blood is still fluid. This may result from either of two factors—it may be due to the fact that there is little tissue destruction and so thrombokinase is absent and hence clotting is greatly delayed, takes place only partially, or does not occur at all; or it may be that clotting does not take place because, by the action of the lung in expanding and contracting, the blood is defibrinated and so in effect cannot clot. From examinations of large numbers of cases it would appear that no single hypothesis can fit every case; but studies of the calcium content and the clotting and prothrombin times of the blood from the haemothorax show that both the above factors play a part, and which of them predominates would seem to depend on the nature of the injury. Often tissue destruction (as in the cases cited) is considerable, ribs may be fractured, and the muscles and the parietal pleura torn, yet the blood may be still fluid. Fibrin in large amounts may be present on the lung surface, and thus defibrination may have taken place. In other cases the tissue destruction may be small and the absence of thrombokinase may be the deciding influence.

It has been stated that the fibrin deposited on the pleura may organize and so prevent the lung re-expanding. This would seem possible in cases in which lung collapse is of some duration, but I have never met with it in this series.

2. *Compression or Collapse of Lung.*—Compression of the lung may be acute as in pneumothorax or may come on gradually as in haemothorax. These cases of haemothorax may not reach clinical significance until 12 to 18 hours, but may finally attain enormous proportions, even as much as 3,000 to 5,000 c.cm. Here the heart is pushed over to the opposite side and the circulation and aeration of the opposite lung are severely impaired. Massive collapse is a rare occurrence; but its possibility should be kept in mind, as early diagnosis is of importance. It would appear to be due to loss of the cough reflex by shock or pain, so allowing mucus to collect and finally block a bronchus, or else a blood clot may find its way from the site of lung injury and likewise cause blockage. When this type of collapse is only temporary no definite pathology may be found in the lungs and complete recovery may take place, but infection or even bronchiectasis is always a possibility if the condition is of any standing.

3. *Infection.*—Even with the introduction of the sulphonamides infection is still the dread of the lung surgeon. In closed injuries of the chest it is rare for the pleura to be infected until later in the course, but pneumonic changes may set in early. They have no special pathological features.

Contusions

This group comprises injuries due to direct violence; these occur chiefly in younger persons whose ribs are still elastic, and so the underlying structures, heart, and lungs can be contused without actual external injury or fracture of the ribs themselves. I also place in this category an indefinite type of lung injury with an intact thorax which has been reviewed by Fallon (1940). He described the case of a medical student who was knocked down when boxing and later developed a cavity in the left lower lobe with a fluid level, a condition which resolved spontaneously and resulted in full recovery. Here the pathology is indefinite, but in this series of war injuries the basic lesion is more easily recognized.

(*a*) Cardiac Contusion

That there can be contusion of the myocardium without any evidence of external injury or fracture of the ribs or sternum has been known for some time, and Barber (1938, 1940) has reviewed the effects of trauma on the heart and discussed the significance of myocardial contusion. He concludes that, while it is a definite pathological entity, the clinical diagnosis is difficult and "more cases of heart disability following trauma are overlooked than are diagnosed by mistake." Anderson (1940) has reviewed the literature on non-penetrating injuries to the heart and reported a new case. He states that injuries to the heart by non-penetrating blows are commoner than has been supposed, and discusses the pathological and clinical picture. Warburg (1938), in his classical monograph, reviews 202 cases of traumatic injury to the heart. Bright and Beck (1935) have also contributed to the literature, while Moritz and Atkins (1938) have made an interesting experimental and pathological study of cardiac contusion. The importance of the subject is thus now generally recognized, and in all cases in which the history may point to injury to the chest wall evidence of cardiac trauma should be sought for clinically and the possibility of a cardiac element in the general picture eliminated. The whole condition may of course be subclinical, and complete recovery may take place. When it is at all severe we get evidence of myocardial damage such as cardiac irregularities or the development of angina pectoris, valvular lesions, or pericarditis.

In my war experience traumatic cardiac lesions have occurred in two definite circumstances—either from direct trauma to the chest or as a feature of blast injury. Owing to the nature of blast and the difficulty of getting an accurate story of the complete incident it is often impossible, when a bomb explodes, to say that the victim is not either hit directly or thrown against a firm structure, suffering direct violence to the chest. Since the difficulty of differentiating the cause exists, and since the subsequent pathological picture of the cardiac lesion is similar, I shall deal with both groups together. Trauma of the heart may cause contusion of the myocardium, traumatic pericarditis, or rupture of the valves and great vessels. Those subjected to war injuries are as a rule healthy persons, and so previous cardiac lesions do not complicate the picture.

Myocardial Contusion.—If we examine a transverse section of the thorax and note the position of the heart in relation to the spinal column behind and the sternum in front we can see how it is possible, especially in young subjects with elastic ribs, for the heart to be damaged without injury to the chest wall itself. Any part of the myocardium may be involved, but it would seem that the anterior surface of the ventricles was most often affected. At necropsy the pericardial fluid may be blood-stained and increased in amount. The myocardium at the site of contusion is dark and haemorrhagic, and has a naked-eye appearance not unlike an infarct. Microscopically, in recent cases there are subpericardial haemorrhages and evidence of tissue disorganization and generalized congestion. If the lesion is extensive and involves a considerable thickness of muscle the softening which occurs before organization may be serious enough to cause rupture of the myocardium as in the case reported by Priest in 1939. Older cases in which organization has taken place are particularly difficult to differentiate from an infarct. The history, the site of the lesion, and the state of the coronary vessels must be taken into account.

Pericarditis.—Traumatic pericarditis is rarely serious, though Warburg (1938) found a purulent pericarditis in five cases of his series, and described a case of Pick's disease occurring two years after an injury. As most of our cases of cardiac injury due either to direct violence or to blast resulted in death soon after the injury, pericarditis was not seen.

Valvular Lesions and Rupture of Great Vessels.—Kahn and Kahn (1928) have shown, by striking the chest of a corpse, that it is possible to rupture a valve and, though I have never actually succeeded in doing this, several workers have recorded similar results. Moritz and Atkins (1938) in their experimental work report no rupture of valves in any of the 32 dogs whose hearts were subjected to trauma. Elsewhere I have recorded a case of ruptured aorta and tearing of an aortic cusp as a result of blast, but this lesion would appear to be rare.

(*b*) Pulmonary Contusion

In these days of blast, when the proper interpretation of the lesions incidental to bomb explosions is so essential, cases of pure pulmonary contusion are very important, and so a description of one may be of interest.

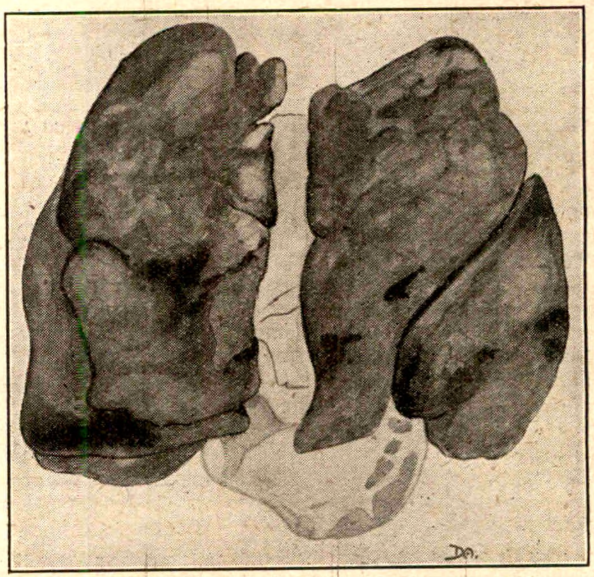
A soldier aged 26 was admitted to hospital, having been shot through the left shoulder with a rifle bullet fired at a distance of approximately 20 yards. The bullet passed over the neck of the humerus, hit the clavicle, fracturing it in several places, and had apparently been deflected up into the neck, passing behind the cervical vertebrae and emerging from the neck posteriorly on the right side. The patient died 6 hours later owing to shock and haemorrhage from the neck wound. The upper four ribs had been driven in without being fractured, and at necropsy the apex of the left upper lobe was contused, the pleura being intact. There was about 100 c.cm. of blood-stained fluid in the left pleural space. The left lung was congested throughout and the apex was the seat of a large area of haemorrhage situated on the lateral and anterior surface—e.g., peripheral rather than central. Anteriorly its border was very irregular and showed linear markings corresponding to the 2nd and 3rd ribs. The right lung was also congested throughout, but no definite areas of haemorrhage were present. There were also suggestions of linear markings on this side.

Histological examination of the left apex (the site of the contusion) showed alveoli packed with red blood cells. The capillaries were congested and a few were ruptured. The alveoli were intact and there was no evidence of oedema. The main feature of the left lower lobe was slight generalized congestion, but the whole of the right lung showed scattered areas of haemorrhages into the alveoli and generalized capillary congestion. Slight oedema was present and some of the alveoli were ruptured.

The interpretation of this case would seem to be that direct trauma affected the left upper lobe, causing haemorrhage throughout that lobe. The left lower lobe apparently escaped, but the right lung suffered contrecoup injuries, which produced naked-eye and microscopical pictures identical with those found in pulmonary concussion. It would thus appear that direct injury can produce all the essentials of a blast injury—an observation the importance of which will be discussed later.

Blast Injuries

Blast injuries, especially as they affect the lung (pulmonary concussion), have provided one of the most interesting studies in this Command during the present war. The weight of the aerial attack and the structure of many of the shelters made its incidence high. I have had the opportunity of examining a number of large and small series of cases, as well as many individual ones, and so have been able to get some idea of their basic pathology and usual clinical course.



Typical appearance of a lung in cases of blast injury. Note the general congestion, with darker areas of haemorrhage. On the right lung these darker areas are located along the interlobar septa, and on the left they have taken on a linear distribution.

In blast the lung picture is usually one of haemorrhage. These areas of haemorrhage are scattered throughout the whole of the organ, and are found deep in the lung substance as well as being subpleural. There is no suggestion of consolidation, and the general feel of the lung is rubbery. Dark linear markings are present in adults just as often as in children, and from a study of the lung position in some of our later cases I regard these, especially in older people, as corresponding to intercostal spaces rather than to ribs. Apart from these intercostal markings there is no special predilection for the areas of severe haemorrhage, but as a rule the regions most affected are those parts of the lung which expand indirectly—i.e., the posterior surface of the lung apex and the posterior surfaces of the lungs in contact with the spinal column and attached segments of the ribs—and laterally the maximum effect is in the middle parts—i.e., opposite the 5th, 6th, and 7th ribs (as shown in the accompanying illustration). The picture is bilateral, though one lung may be affected more than the other. However, there is no general rule as to the position of the body in relation to the source of blast and the severity of the haemorrhage, since other factors operate. Apart from this picture of haemorrhage and emphysema the only other naked-eye appearance of significance is the presence of subpleural bullae. These occur in only a small proportion of cases, but are very definite. The pleural spaces usually contain blood-stained fluid.

The histological picture of those dying early is what one would expect from the macroscopic appearance. There is widespread congestion, often with intra-alveolar haemorrhage to a very marked extent. The alveoli may be ruptured and mild oedema may be present even in the early stages. There is no definite relation between the size of the haemorrhages and the survival period, but most of the bleeding would appear to take place almost at once. Later, fibrin formation and round-cell infiltration occur.

The after-course of these cases is gradually becoming clearer. That many are mild enough to be subclinical throughout their whole course is apparent from post-mortem studies of patients subjected to blast and dying later of a complicating lesion. The incidence of blast lesions of a minor degree among air-raid casualties would appear to be high. They seem to clear up in time with little symptomatology and no sequelae. The clinical cases pass through a stage of bleeding which is probably quite short (4 to 6 hours), then a stage of coagulation, absorption, and repair somewhat as occurs with a pneumonic exudate. Patients who die do so as a rule because of injuries elsewhere, but those subjected to pure blast seem either to die in the first few hours or to recover if no complication sets in. The course of these cases, however, is beset with three dangers: (1) development of pneumothorax; (2) acute oedema and heart failure; (3) infection—bronchopneumonia.

One of my patients developed a pneumothorax shortly after admission to hospital and died within 24 hours. A subpleural bulla which had ruptured was present on the surface of the right lower lobe. The histological picture of the lungs was characteristic of blast injury. He had received no direct chest injury. Cases such as the one described below would appear to be those most liable to develop acute oedema and heart failure.

A man aged 24 was standing at the entrance of a shelter when a bomb exploded 20 ft. away. The blast was considerable and a bomb splinter injured his foot. On admission to hospital he had lost a considerable amount of blood, was shocked, and as amputation of his foot was necessary a transfusion of whole blood was given. He died next day with clinical signs of right-sided heart failure. At necropsy were found dilatation of the heart and extensive pulmonary oedema superimposed on blast changes—a condition confirmed by histological examination.

Finally, since we are dealing with a lung which is full of haemorrhagic areas and with a patient whose vitality is lowered by shock and whose treatment demands a certain amount of immobility, we would expect infection to develop. On the whole, however, a pneumonic process was comparatively rare in this series.

An aspect of blast injuries which has received little attention in the literature is the mediastinal changes which occur. I have found contusion of the myocardium in several cases, and, in one, rupture of the aorta, while many have petechial and small haemorrhagic areas in the anterior mediastinum, all pointing to mediastinal trauma. It is important, therefore, for the physician to examine all cases of blast with respect to cardiac symptoms such as tachycardia, dilatation, and cardiac irregularity.

Two Problems of Blast Injuries

In the elucidation of blast injuries two problems present themselves: What is the mechanism of the production of the *lung damage*? and What is the *cause of death*? Two theories can explain the lung injuries—direct trauma to the chest wall, or a force acting down the trachea and bronchi, causing either a negative or a positive pressure wave. Direct trauma would seem to explain the condition much better than any other theory, and, indeed, is probably the only one which at the same time accounts for the lung damage and mediastinal injuries as well as the abdominal lesions found. It is probable that in pulmonary concussion we are not dealing with a new condition but with contusion of the lung caused by a fresh set of circumstances as a result of war. When a bomb explodes, the body is at once placed in a medium of high pressure such as that in which a diver would find himself if unprotected at a depth; and so the abdominal and thoracic cavities, with their relatively weak walls, give way before the external pressure, and the underlying organs are damaged, especially elastic organs such as the lungs.

Four main theories have been advanced as to the cause of death in these cases. First, since the lungs appear to suffer most, many workers have thought that death might be due to the pulmonary haemorrhages and interference with respiratory function. Examination of blast cases shows that, while this might be true in some cases, the lung injury is usually not sufficient to cause death. Secondly, some have postulated a cerebral cause of death. The lesions in the brain in those dying immediately or soon after injury are very indefinite, but if we postulate a wave of positive pressure coming up from the abdomen and thorax via the blood stream and damaging the vital centres no gross pathological change would be expected. Thus, while positive evidence is scanty still, this theory is the most reasonable one yet formulated. Thirdly, death may be cardiac in origin. I have stressed the importance of injury to the heart in cases of blast, and there is quite a chance that ventricular fibrillation may occur and account for death on certain occasions. Fourthly, air embolism may be a possible cause of death. In blast the body is suddenly immersed in a wave of high velocity and pressure, the picture somewhat resembling that of a diver released unprotected at a depth. The gaseous content of blood and tissue fluids may thus be increased even though the effect of the blast wave is momentary. Then, as the effect of the blast wave passes off, the body is faced with an impossible situation, as in the case of a diver immediately brought to the surface, and air embolism is the result.

Pulmonary Fat Embolism

Reported cases of pulmonary fat embolism have rapidly increased in number in recent years owing to wider recognition of the condition. This is usually a sequel to fracture of a long bone, especially the femur, the fat gaining entrance to the blood stream and being carried to the lungs; thence it passes into the general circulation, causing pathological changes in the brain, kidneys, and heart muscle.

In a series of cases reported by Wilson and Salisbury in 1942 the main macroscopic lung findings were haemorrhage and mild oedema. The congestion and haemorrhage may be considerable, but I did not see the large subpleural haemorrhages described by Robb-Smith. These are much more characteristic of pulmonary concussion. Small areas of subpleural haemorrhage may be present. On cutting into the lung surface the picture is one of extreme congestion with small areas of haemorrhage. Microscopically, fat can be demonstrated in fresh preparations by Robb-Smith's technique, though I have found that staining the lung tissue with Wright's stain gives more convincing results. When stained with osmic acid, fat droplets can be seen in the capillaries. The alveoli contain red cells and oedematous fluid, the red cells being much less numerous than in blast cases, but the oedema is usually much more pronounced.

Summary

The main pathological features occurring in closed chest injuries are outlined.

In laceration the chief danger is haemothorax, the pathology of which is here dealt with.

The pathology of pulmonary contusion is compared with the effect of blast, and the evidence for regarding pulmonary concussion as being due to the direct trauma to the chest wall is outlined.

The importance of cardiac lesions in chest injury is stressed.

Lung changes in cases of fat embolism are briefly discussed.

I wish to thank Col. A. S. Heale for permission to publish this paper. I am also grateful to Prof. Debono for his co-operation; to Prof. Bernard, Director of Public Health, and the authorities of the Central Civil Hospital for allowing me such free access to their wealth of material; to the staff of the General Hospital; and to Majors A. Charles and R. E. Tunbridge, R.A.M.C., for much help and criticism. Major D. J. S. Armstrong, R.A.M.C., supplied the drawing that is here reproduced.

AN OUTBREAK OF EPIDEMIC CATARRHAL JAUNDICE

BY

L. R. L. EDWARDS, M.R.C.S., L.R.C.P., D.P.H.

Senior Assistant Medical Officer of Health, County Borough of Wolverhampton

A review of accounts of outbreaks of epidemic catarrhal jaundice occurring in this country shows that the majority have affected rural areas. There have been exceptions, for Morgan and Brown in 1927 described an extensive outbreak in the Midlands in which 200 persons were affected, with one fatality. A previous outbreak in Staffordshire was described by Frazer in 1935, although Barber (1937) regarded this epidemic as one of infective hepatic jaundice. It would appear that the town-dweller has relative immunity from this disease. The following account of an outbreak of epidemic catarrhal jaundice occurring in an urban area may therefore be of some interest; it is published in the hope that other writers may suggest further aetiological factors and effective measures of control.

Incidence

A total of 64 cases occurred in an outbreak which has lasted for eight months. This figure is estimated to represent about 80% of the total number of cases. The outbreak was chiefly among school-children, and the few adults affected were mainly young school-teachers. The epidemic appeared to be confined to one school for several months, but after a summer holiday, during which only a limited number of children attended school, the disease made its appearance at several other schools. Practically all of these schools were in the northern part of the borough.

The seasonal incidence of the disease is usually in autumn and winter, but this epidemic began in the spring and continued over the summer. The sex incidence was about equal. The highest age incidence occurred between 6 and 10 and between 20 and 30 years. It was noted that in no case were more than two members of a family affected. School-teachers were particularly at risk to the disease.

Age	Males	Females
4–5 years inc.	5	3
6–10 „ „	20	22
11–15 „ „	3	3
20–30 „ „	Nil	5 (4 school-teachers)
Over 30 „	1	2 (1 school-teacher)
Total	29	35

Aetiology

The evidence points to a contact at school. The epidemic had not the explosive nature usually associated with outbreaks of food-poisoning due to contaminated food, milk, or water. Further, the water supplies of the borough are chlorinated, and school milk supplies are bacteriologically clean. Again, the infant and junior departments in the school mainly affected received milk supplies from different sources. The disease appeared to pick out the children in twos and threes from each class, and the available evidence pointed to a close personal contact, with droplet infection as the probable means of spread. No bacteriological examinations were carried out, but reports of previous epidemics show that they are negative and that the probable cause of the disease is a filterable and ultramicroscopic virus. There was no particular incidence of sore throats or enteritis. While an epidemic of enteritis occurred in some of the schools of the borough, this was seasonal, and, further, there was no especial incidence of cases of catarrhal jaundice at any of them.

Clinical History

From descriptions given by various medical practitioners, and from visits made to many of the cases, the following clinical report has been compiled.

The spread of the disease suggests that the incubation period varies between three and four weeks. In the prodromal period malaise and anorexia may be present, but more often the disease started with vomiting, sometimes associated with severe upper abdominal pain. The attack of vomiting lasted from a few days up to a week, and resembled cyclical vomiting. Constipation was usual, though a few cases had diarrhoea until the onset of jaundice. In some cases jaundice limited to an icteric tinge of the conjunctiva, and nausea, were the only symptoms, and the illness cleared up in less than a week. With the cessation of vomiting, jaundice appeared first of all in the conjunctiva, and in the course of a day or two spread to the skin of the face, trunk, arms, and lower limbs. The colour deepened to a canary yellow, and the motions became clay-coloured and the urine orange-coloured. Pyrexia was variable in occurrence and in severity. Headache was sometimes severe. There was well-marked enlargement of the liver, with tenderness over the gall-bladder. The spleen was enlarged. The jaundice lasted a variable period from a few days up to two weeks, and gradually disappeared in the reverse order. The faeces and urine became normal a few days before the jaundice disappeared from the skin.

Examination of blood films from five of the cases in the acute stage showed a well-marked leucopenia with a relative lymphocytosis An increase in monocytes was noted in each film. In the acute stage in adults there was sometimes complaint of severe pains in back, arms, and legs. No epistaxis or petechial rashes occurred. Despite the severe jaundice, itching of the skin was present in very few cases. Convalescence was marked by the development of excessive appetite. In a few instances some degree of furunculosis occurred.

Vomiting in the acute stage is usually a feature; Lisney (1937) attributes this to duodenitis. According to Pickles (1930), the severity of the upper abdominal pain may suggest a perforation.

Differential Diagnosis

The diseases to be excluded are Weil's disease, infective hepatic jaundice, simple catarrhal jaundice, enteric fevers, and acute yellow atrophy. Weil's disease is marked by epistaxis and petechial rashes, with high fever, severe nervous disturbance, blood leucocytosis, and the identification of leptospira in the blood. Infective hepatic jaundice is characterized by an absence of pre-icteric symptoms, and the jaundice is less marked. Simple catarrhal jaundice occurs sporadically. The symptoms are very similar to those of epidemic catarrhal jaundice, and this complaint may be an interepidemic type. Jaundice seldom occurs in the enteric group, while acute yellow atrophy is a very rare disease.

Spread of the Disease

The spread of the outbreak is well illustrated by the experience of the junior department of one of the schools.

Class: Boys aged 7
  C. H.—Away Sept. 24
  M. R.— „ Oct. 21
Class: Boys aged 10
  A. H.—Away May 19
  T. W.— „ June 18
Class: Girls aged 9
  B. F.—Away July 27
  J. M — „ Sept. 4
  M. G.—Oct. 3 (3 days' jaundice; not excluded from school)
  Miss S. (teacher of the class)—Away Oct. 10
  B. T. (daughter of Miss S.'s landlady)—Away Oct. 29
    No cases were reported from B. T.'s school at this time.

The evidence suggests a spread of the disease from child to child and from child to school-teacher, and that very close personal contact was necessary.

It was interesting to note that no member of a class of nursery children, in the charge of a school-teacher suffering from the disease, contracted the illness. It was observed that the incidence in children under school age was low.

Clear cases of infection of two school-teachers who were friends occurred at one school, with an interval of three weeks between the illnesses. No children in their respective classes were affected, although the disease was prevalent in the school. It seems that the infective period is a short one, and Pickles (1939) states that further evidence of this is noted in the periodicity of attacks. A two-weeks isolation period was not followed by any return case.

Conclusions

It appears that epidemic catarrhal jaundice spreads chiefly in school-children, but young school-teachers frequently contract the disease.

There is probably among the general public a lack of appreciation that cases of jaundice occurring in children may be infective.

This disease seems to have a short infective period, to be spread by close personal contact, and to have an incubation period of between three and four weeks.

It is spread through an ultramicroscopic virus, notably by way of the upper respiratory tract. No effective measure of control appears available. School closure leads to scattering of the disease over a wider area.

A period of two weeks' isolation seems to be sufficient. This was carried out in the present outbreak, and there were no return cases.

The town-dweller appears to have little immunity from the disease, which spreads in the same manner as in rural areas. Two age groups are chiefly affected—6 to 10 years and 20 to 30 years. It is possible that the former group is affected because children of this age may be more sociable in their habits.

An epidemic of enteritis may occur coincidently with an epidemic of catarrhal jaundice if either occurs out of season.

I wish to express sincere thanks to Dr. R. H. H. Jolly for permission to carry out this investigation.

PEDICULOSIS CAPITIS AND INTELLIGENCE IN W.A.A.F. RECRUITS

BY

HENRY R. ROLLIN, M.B., Ch.B., D.P.M.
Flight Lieutenant, R.A.F.V.R.

Recently much interest has been aroused in the question of the correlation of parasitic infestation, particularly scabies, with intelligence. The results so far have been controversial. Hodgson (1941a, 1941b) found that the incidence was higher in men of inferior intelligence, whereas Mellanby *et al.* (1942), attempting to corroborate Hodgson's work, found that men suffering from scabies were mentally an approximately normal sample from the Army.

The Investigation

The opportunity for the present investigation occurred during psychiatric work at a large W.A.A.F. depot when selecting recruits suitable for trade training, those suitable for acceptance in the Service but not for trade training, and those unlikely to become efficient airwomen. Broadly speaking, the problem resolves itself in the main into one of intellectual grading, although obviously other factors, such as personality, temperament, previous work, and social history, enter too. The correlation between parasitic infestation and intelligence therefore has a practical aspect: thus in cases in which doubt occurs, opinion may be, and in fact has been, swayed by the incidence of scabies, pediculosis, or, as sometimes happens, both.

In the W.A.A.F. pediculosis capitis is by far the greatest of all parasitic problems, and because of the relatively large numbers infested the correlation of intelligence and infestation was attempted. All W.A.A.F. recruits on arrival at the depot are examined for pediculosis capitis by specially trained medical orderlies as part of the routine F.F.I. examination. Those found to be infested are detained in "head huts" for treatment, and their intelligence tests, psychiatric examination if necessary, and trade selection are postponed till such treatment is completed.

The intelligence test used on all W.A.A.F. recruits is the "G.V.K." test, devised by Dr. W. Stephenson of Oxford. This consists of three group paper and pencil tests applied by specially trained W.A.A.F. officers and airwomen under standard conditions. They are divided in accordance with the Spearman approach to intelligence into "G" tests (general analytical intelligence), "V" (verbal intelligence), and "K" (practical-mindedness). The raw score on these tests is converted into percentiles expressing in percentage terms the standing of a recruit in relation to other recruits.

Results

The G.V.K. scores expressed in percentiles of 312 recruits after treatment for pediculosis capitis are given in Table I. The percentile G.V.K. scores of 312 unselected recruits found to be free from pediculosis capitis are given in Table II.

TABLE I.—*G.V.K. Scores in Percentiles: Recruits Treated for Pediculosis Capitis*

Percentiles	Number of Recruits		
	G	V	K
90–99	7	6	0
80–90 ..	15	22	0
70–80 ..	26	14	2
60–70 ..	21	15	3
50–60 ..	31	19	8
40–50	28	22	9
30–40	42	31	32
20–30	44	34	47
10–20	41	64	57
0–10	57	85	154
Total	312	312	312

TABLE II.—*G.V.K. Scores in Percentiles: Unselected Recruits free from Pediculosis Capitis*

Percentiles	Number of Recruits		
	G	V	K
90–99	70	53	7
80–90 ..	65	65	17
70–80	44	42	12
60–70 ..	23	19	24
50–60	24	21	33
40–50	25	20	39
30–40 .. .	23	27	44
20–30	25	19	51
10–20	8	27	44
0–10 . ..	5	19	41
Total	312	312	312

A comparison of the two tables shows very clearly that the number of recruits with the lowest percentile scores is greater in all three tests in those treated for pediculosis capitis. Thus, in G, V, and K there were respectively 212 (69%), 236 (76%), and 299 (96%) with percentile scores of between 0 and 50 in recruits treated for pediculosis capitis, as compared with 86 (28%), 112 (36%), and 219 (71%) in those found on initial F.F.I. examination to be uninfested.

Summary

On initial F.F.I. examination 312 W.A.A.F. recruits found to be infested with pediculosis capitis were treated and then given the Stephenson G.V.K. intelligence tests. The scores after

conversion into percentiles were compared with the percentile scores of 312 unselected recruits who were uninfested.

There was a marked difference in the scores of the two groups, the lowest scores in all three tests being found in the infested group, suggesting that pediculosis capitis is more prevalent among the less intelligent recruits.

I wish to thank A.S.O. Comley, W.A.A.F., and Corporal (now Sergeant) Minnitt, W.A.A.F., for their very valuable assistance.

TREATMENT OF MALARIA IN ENGLAND

BY

ALEC WINGFIELD, M.D., M.R.C.P.

Physician with Charge of Out-patients, Seamen's Hospital; Physician, E.M.S.

The manifestations of malaria as seen in England are almost protean in appearance and character, so it is probable that many cases are overlooked. In particular this is true of the subtertian, in which the classical periodicity is not always to be found and which may indeed show no fever. Most of the cases seen in England are probably examples of relapse, because patients generally have resorted to some antimalarial drug with the onset of the primary fever in the Tropics. Frequently, however, the dosage which they use is so inadequate that return to a colder climate precipitates an attack.

During a period of a little more than 18 months there have come under observation and treatment at the Seamen's Hospital 60 cases of malaria in which the diagnosis has been confirmed by finding parasites in blood films. The numbers may appear trifling to those who are accustomed to this infection in regions where it is indigenous, but to English practitioners they may seem formidable. In the course of diagnosis and treatment some problems have appeared, but with few exceptions it has proved possible to adhere to a standardized procedure. Certain variations, both in the nature and in the length of treatment, have been unavoidable as a result of exigencies of war; but the main therapeutic scheme has been similar in 57 cases of subtertian malaria. The overwhelming preponderance of subtertian infection was natural, since most of the patients had been infected in Freetown, Sierra Leone, where other species of malaria are almost unknown. In 40 a history of previous quinine therapy was obtained, but, as many of the patients were foreigners and the language difficulty sometimes did not permit of an accurate and detailed statement, it was not always possible to find out whether quinine had been taken prophylactically or therapeutically. Previous quinine therapy had undoubtedly modified the clinical picture very greatly and increased the difficulties of diagnosis. One patient at least, dissatisfied with delay while the diagnosis was being established, continued to take quinine surreptitiously while in hospital, thus rendering the difficulty even greater.

Diagnosis

Throughout the period under review it has been considered essential to demonstrate malaria parasites in the blood film before starting specific therapy, but in order not to overburden the pathological service an attempt has always been made to establish a clinical probability before calling in laboratory aid. Of the patients 44 had fever at the time of admission, while 24 complained either of shivering attacks or of malaria, and in these cases the probability was considered to be sufficiently great to justify blood examination; but during the same period more than 40 men were admitted diagnosed wrongly as cases of malaria either on their own initiative or by the masters of their ships, and among the various causes of symptoms "influenza," bronchitis, cystitis, and tuberculosis were found to be the most important in order of frequency. Any patient who develops a fever after recently returning from the Tropics is, of course, to be suspected of malaria; but it is just as important to recognize the multitude of other febrile conditions which *may* be present as it is to diagnose malaria correctly when it is present. In any suspicious case blood films must be examined on more than one occasion, and the blood should preferably be taken when the fever is at its highest. The use of a preliminary injection of adrenaline half an hour before the taking of blood films is referred to later. The character of the fever was not found very helpful, and only two cases remained undiagnosed for long enough to reveal tertian periodicity.

Among the more baffling symptoms generalized aching pain in the limbs was described in 4 cases, abdominal symptoms in 3—one of which cases was admitted as an acute abdominal emergency and one on account of bloody diarrhoea—and 10 gave headache as their main complaint. One patient was admitted unconscious, with high fever. Cerebral malaria was promptly diagnosed, since it is an established custom to regard all pyrexial comatose patients as suffering from malaria until some alternative diagnosis is established. In 43 the spleen was palpable, but in only 5 was more than a 2-finger enlargement recorded, while in a certain number of cases the organ could be felt only by deep subcostal palpation with the patient lying on his right side. Considerable practice is necessary to detect lesser degrees of splenic enlargement, and it is slight splenomegaly which is most likely to help in diagnosis of doubtful cases. Anaemia of varying degree was present in almost every case, but haemoglobin estimations were made only in those cases in which, on clinical grounds, a severe depression was anticipated. Out of 22 cases in which the haemoglobin was determined 17 gave values below 70%.

The blood examinations for parasites were carried out by Dr. Arthur Davies; he recorded malignant tertian rings alone in 39 cases, rings and crescents in 13, and crescents only in 5 cases. Benign tertian parasites were found in 2 cases and quartan malaria in a single instance. One of the benign tertian patients had apparently been infected either in South America or in Panama, while the other had spent some years in India, although he had been for a few weeks in Freetown also. The quartan infection apparently originated in the Philippines. Out of 60 cases in the series, parasites were found at the first examination in 42 and at the second examination in 13, while in the remainder multiple examinations were necessary. In 2 cases parasites were discovered only in films taken after the injection of adrenaline, given as a simple subcutaneous injection, usually before the second examination. The intravenous technique of Ascoli was not employed.

Treatment

The benign tertian and quartan infections were treated with quinine only. The subtertian infections were treated with a combination of mepacrine (atebrin) and quinine, pamaquin (plasmoquine) being given subsequently to those patients in whom the sexual forms of the parasite had been found. In all cases two equal courses of mepacrine 0.1 g. t.d.s. combined with quinine in varying dosage were given, while in the intervening period quinine alone was used. The original course lasted 15 days, but later the course was extended to 21 days: throughout the series, however, it was divided into three equal periods—two of mepacrine and quinine together and one of quinine alone. In the original course quinine 10 gr. t.d.s. was given, but this was subsequently reduced to 5 gr. b.d. without any adverse effect on the therapeutic result being noted. The total dosage now given in 21 days is 4.2 g. of mepacrine and 210 gr. of quinine. The course is therefore now as follows:

First week: Mepacrine 0.1 g. t.d.s.; quinine 5 gr. b.d.
Second week: Quinine 5 gr. b.d.
Third week: Mepacrine 0.1 g. t.d.s.; quinine 5 gr. b d.

After completion of the above course pamaquin was added in cases in which crescents were present.

The considerable total dosage of drugs was regarded as justified when treating patients in England, where there is no danger of reinfection and where the number under treatment is inevitably so small. No case of quinine sensitivity was encountered, and only 4 developed yellow mepacrine pigmentation. Of these, 3 were but slightly tinged; but the fourth patient, who had been certified as fit for duty, was sent back with a pointed letter about the fitness of "jaundiced" patients.

Fortunately, mepacrine pigmentation scarcely ever tints the conjunctivae, so that differential diagnosis is easy.

The dosage of pamaquin was 0.01 g. t.d.s. for 3 to 5 days. It was given alone subsequent to the routine course. All patients received adequate therapeutic doses of iron.

In a few who were seriously ill on admission, including the cerebral malaria case, intramuscular quinine was injected with dramatic results, but it was never necessary to give more than two doses. The injections are painful and may give rise to necrosis, but they are not often necessary in this country. Since this series was concluded a trial has been made of an almost painless quinine solution, but its therapeutic activity seems to be far below that of the oral course which has here been described.

Results

The clinical results have been most gratifying and there have been no deaths in the series. All the patients were in good health when discharged, none has returned with a recurrence, and we have had no inquiries from other hospitals for clinical notes of these patients. However, sailors are nomadic persons, and it may well be that relapses have indeed occurred.

In the 44 patients who had fever on admission defervescence occurred on an average less than 24 hours from starting treatment, and the longest time fever persisted was 72 hours, in two cases only. The average stay in hospital was 27 days, but in most cases a part of this time was spent at our convalescent home, and some of the patients required treatment for other conditions. If the length of detention should require further justification, it may be found in the imperative need to restore seamen to complete health before permitting them to return to their arduous duties, and, finally, in the need to restore their haemoglobin to normal level.

Summary

A series of 60 cases of malaria, of which 57 were subtertian, is described.

Clinical examination has shown that neither fever nor splenomegaly can always be relied upon to suggest diagnosis, but anaemia is generally present.

A course of treatment combining mepacrine and quinine was found satisfactory.

The results of treatment were uniformly good, but no extensive follow-up was possible.

My thanks are due to Sir Philip Manson-Bahr and to Dr. Arthur Davies for their constant help and advice.

Medical Memoranda

A Case of Extreme Exomphalos

Exomphalos is a well-recognized congenital malformation which is said to occur once in every 6,000 births. It is due to the non-closure of the abdominal wall, presenting a picture which, normal in early development, has persisted to term. The case described is one in which the defect was carried to the extreme.

CASE HISTORY

Mrs. A., aged 20, a primipara, was admitted to hospital in labour. Medical assistance was sought on account of a loop of intestine being delivered with the shoulders. This belonged to the foetus (not to the mother, as the midwife at first thought). Delivery was completed. The child, a female, was in good condition apart from a mass consisting of coils of intestine lying on the abdominal wall. This mass was gangrenous and distended. Removal was the only course open.

Operation was performed an hour after delivery. The object of the laparotomy was to remove the dead tissue and to see the exact nature of the lesion. No anaesthetic was given; and a right paramedian incision was made. The gut appeared alongside the umbilical cord, on the inferior aspect; the latter was normal. The exit was small, approximately an inch across, and the parietal peritoneum ended at the edges of the opening. At the upper end viable intestine was found at the end of the second part of the duodenum, and at the lower end the pelvic colon. At each end the gut was divided and a small tube ligatured in and brought out through the abdominal wound. Apart from a large liver no other abnormalities were seen. During the operation the child did not give any cause for anxiety. It lived for six days, at the end of which death occurred from peritonitis. No other congenital defects were found at the necropsy.

The Specimen.—This consisted entirely of intestine. It began at the third part of the duodenum and ended at the beginning of the pelvic colon.

Small Intestine.—The upper part was discoloured small intestine surrounded by a mass of myxomatous tissue. The mesentery was twisted on its axis, forming a volvulus: from the appearance of the gut it was a recent development, but was not considered viable. Below this the ileum was lost in the large intestine and was found to be an intussusception of the ileo-caecal variety. This was reduced with difficulty.

Large Intestine.—This was very dilated and the taeniae coli were not evident. The contents were fluid and contained much vernix caseosa. The mesentery was very thick, consisting of myxomatous tissue. At the lower end there was a constriction where it was obstructed at the exit from the abdomen.

The intestine thus presented a picture of obstruction of the large bowel with an intussusception and volvulus of the small bowel.

COMMENT

It is considered that the foetus *in utero* had a marked exomphalos containing the major part of the bowel. During the descent in the second stage of labour, lasting four hours, the peritoneal covering was torn off and the large bowel was compressed between the uterus and the foetal abdominal wall, obstructing the blood supply. Ensuing peristalsis resulted in the intussusception. The volvulus, as mentioned, was recent, and was formed towards the end of the second stage of labour.

There has been much discussion as to the absorption of glucose from the stomach. In this case part of the duodenum was present; but it was considered worth while to investigate the blood sugar after a known dose of glucose. 10 g. of glucose was given by mouth, and the blood sugar was estimated at half-hour intervals, the blood being taken from the anterior fontanelle. The result showed a curve which approximated to the normal adult curve, though the basic level was very low; the fasting level was 44 mg. per 100 c.cm. Considering that the child lived for six days on glucose given by mouth, good evidence is afforded that glucose is absorbed from the stomach and upper duodenum.

I wish to express my thanks to Dr. Daley, Medical Officer of Health, County Hall, for permission to publish this case; to Dr. E. Moore, obstetrician, Lambeth Hospital, for calling me to see the case; and to Dr. R. F. L. Hewlett, group pathologist, Lambeth Hospital, for the blood-sugar estimations.

Lambeth Hospital. R. F. HENDTLASS, M.R.C.S.

Interstitial Emphysema during Labour

The following case is reported in view of its unusual character and rarity.

A primipara aged 17 was admitted to hospital in the early stages of labour and suffering from acute nasal catarrh with severe bronchial cough. Her previous medical history was good, with the exception of her grandfather, who had died of pulmonary tuberculosis, and her father, who had died at the age of 38 from meningitis. Labour started at 2 a.m. on Oct. 13; the membranes ruptured at 11.35 a.m. on the same day, and there was full dilatation of the cervix at 11.15 p.m. The second stage was characterized by really severe pains. The baby was born at 1 a.m. on Oct. 4.

At 12 midnight, one hour before the baby's birth, it was noted that the right side of the mother's face was rapidly swelling, and she complained of stiffness on that side of the neck. Within a quarter of an hour the face was completely unrecognizable: the eyes were quite closed and the cheeks had merged flush with the nose, and the lips were so swollen that the patient had difficulty in speaking. The swelling involved the head, including the crown of the scalp, the neck, and the upper part of the chest; in diminishing severity it also involved the whole area back and front of the chest down to the costal margins. The diagnosis of interstitial emphysema was made, all areas emitting the characteristic crackling crepitus and the skin giving the resonance to light finger-tapping similar to that of the surface of a sorbo ball. The pelvic measurements were not unduly small, and the baby at birth weighed 7 lb. 8 oz. The total length of labour was 23 hours 10 minutes. On clinical examination no chest lesion could be detected, neither could the patient recollect any special sensation in her chest before the onset of emphysema. An *x*-ray examination of the pulmonary fields was negative and the blood sedimentation rate normal. One week after labour the greater part of the swelling had subsided and the only crepitus that could be elicited was situated over the upper part of the chest on each side of the sternum. The puerperium was uninterrupted, and at no time did the patient appear to be affected by her condition.

ROGER STANLEY.

E. E. Katwinkel (*New Engl. J. Med.*, 1942, **226**, 419) records a case of typhoid fever in a woman, aged 59, in whom sulphathiazole and sulphanilamide in no way influenced the course of the disease and failed to clear the stools of *Bact. typhosum*. The stools, however, became and remained negative after eight days of intense sulphaguanidine treatment.

Reviews

ANATOMY OF THE CENTRAL NERVOUS SYSTEM

Neuro-Anatomy. By Walter R. Spofford, B.S., Ph.D. Oxford Medical Outline Series. (Pp 110. 12s. 6d) London, New York, Toronto: Oxford University Press.

That there is a demand for books dealing in detail with the complicated anatomy of the central nervous system is evidenced by the appearance of two volumes of very different character, published within the last year and bearing the same title, *Neuro-Anatomy*. One of these, a large work by F. A. Mettler, superbly illustrated, and concerned with the topography and microscopic anatomy of the nervous system, was reviewed in these columns on Aug. 29 last (p. 246); and the other now appears as one of the Oxford Medical Outline Series. This has been written by Dr. W. R. Spofford with a view to aiding students who are starting the study of this subject and also to assisting both students and practising physicians to extract from the "vast array of factual data" the fundamental principles underlying the structure of the central nervous system. The author has certainly succeeded in bringing together in a concise form the more essential details of the various tracts and nuclei of the central nervous system, and provision has been made for supplementary notes or drawings by the insertion of blank pages alternately with the text pages. The value of the book, which is wholly lacking in illustrations, would, however, be more than doubled if carefully labelled outline drawings were supplied, so as to enable the beginner to visualize the various centres and nerve tracts in their relation to one another. On the whole the volume is an accurate statement of the accepted facts of neuro-anatomy, but there are some mistakes which require correction, more especially in the spelling of certain proper names (pp. 19, 20, 47) and in the description of the intrapontine course of the fibres of the facial nerve. Except for these minor defects, which can be remedied, the work in its present form will be of value in revising earlier studies and as a book of reference.

THE HOSPITAL BALANCE SHEET

The Hospitals Year-Book, 1942. (Pp. 276.) London: Central Bureau of Hospital Information, 12, Grosvenor Crescent, S.W.1.

The twelfth issue of *The Hospitals Year-Book*, which in addition to its statistical tables relating to voluntary hospitals includes a useful directory of all hospitals, voluntary and municipal, is unavoidably late in publication, and the figures it presents are for the year 1940. That was a highly eventful year in hospital history, owing to many hospitals being put out of action by the enemy, while the demand on others was excessive. But the figures, of course, do not admit of a very close comparison with those of earlier years. One notable feature is the increase shown in the receipts by voluntary hospitals for public services, which in London rose to £1,320,500, or double the figure for 1939, which again was double the figure for 1938; and an even more marked rise was seen in the Provinces and in Scotland. On the other hand, there was a drop in payments by patients. A remarkable feature, all things considered, is the steadiness of legacies. The amount received in this way by the voluntary hospitals of Great Britain from 1936 to 1940 was round about one and three-quarter millions a year, with no more than £100,000 difference between the highest figure and the lowest. Post-war changes are discussed, in particular the question whether the voluntary hospital method of administration, with usually a layman as chief administrator, or the municipal hospital method, with a medical man in that position, is the more likely to be preferred. The writer of an article included in the annual, Mr. Clayton Fryers, house-governor of the General Infirmary at Leeds, puts the case for the retention of the lay administrator method on the ground that a hospital is a complex business undertaking with an annual expenditure (in the larger hospitals) up to a quarter of a million, and a medical man, unless he has had special business training, cannot adequately supervise this side of the hospital's activities.

ENDOTRACHEAL ANAESTHESIA

Endotracheal Anaesthesia. By Noel A Gillespie, D.M., B.Ch, D A (Pp. 187; illustrated. $4.00.) Wisconsin: University of Wisconsin Press.

This comprehensive monograph is a good augury for the future of anaesthesia. More of such excellence is needed. The administration of anaesthesia by the endotracheal route is one of the most valuable of the many arrows which every anaesthetist must now carry in his quiver, and countless lives are made safe every year by its employment. Dr. Gillespie has gathered in small compass most of what is known about this subject, and much of it will be new to his readers. The historical section is of particular interest, and points the moral that advances in anaesthetic technique take place *pari passu* with advances in physiological knowledge. The author gives his personal opinion wherever a variety of views obtains, and his early training in this country shows itself in the ready acceptance most of his views find among British anaesthetists. The experienced anaesthetist will turn the last page of this book with regret, and the novice will find sound advice wherever he reads. One small point for criticism, which stands out only because of the general high level of the rest, is that the description of blind intubation, which is, after all, at the very kernel of the affair, might have been more simple and not made to appear to the uninitiated such a complicated and difficult procedure. Most of the illustrations are good and of great help, but that on page 91 is a little obscure, and that on page 149, perhaps by a fault in printing, appears somewhat strange. Dr. Gillespie's book will be a valuable addition to every anaesthetist's bookshelf.

Notes on Books

The appetite of the general public for books and talks on health is insatiable. It is essential therefore that it should be properly supplied. Dr. HUGH CLEGG's pamphlet *How to Keep Well in Wartime* (issued for the Ministry of Health by the Ministry of Information, H.M. Stationery Office, price 3d.) is a marvel of compression, packed with sound advice and devoid of sentimentality. One's only regret is that the cover should depict a two-child family as typical of our day.

Dr. A. SPENCER PATERSON, psychotherapist in the department of psychological medicine, Middlesex Hospital, has prepared two handy case-taking schemes for the psychoses and neuroses. Each is printed on one side of a card, and they are sold together in a transparent envelope by H. K. Lewis and Co. Ltd., price 1s., postage 2½d. These cards have for some years been issued to medical students during their psychiatric training, and the schemes were reproduced for a wider audience in the *Practitioner*.

Preparations and Appliances

A MERCURIAL DIURETIC

A grain of powdered digitalis three times a day has kept many a patient with auricular fibrillation on his legs for years, and a weekly injection of a mercurial diuretic will often do the same for the patient with heart failure with normal rhythm. Considering the thousands of injections given, serious reactions are few and they are largely confined to patients with renal disease. Mersalyl is the *B.P.* preparation, and this is now being supplied by Boots Pure Drug Co. Ltd. in ampoules of 1 c cm. and 2 c.cm and in tablets which can be taken by mouth in mild cases.

ACETARSOL VAGINAL COMPOUND

Acetarsol vaginal compound (Boots) is a preparation of acetarsol with boric acid and carbohydrate supplied in tablets for local application in the treatment of leucorrhoea associated with *Trichomonas vaginalis* and also with the monilia group of infections. One or two tablets are inserted once or twice daily high up in the vagina. Usually an initial treatment of from two to four weeks is recommended. Remission may occur, even when symptoms are cleared up, and it is therefore advisable to use tablets for two or three months during the three or four days following menstruation, when relapses tend to occur. Samples and literature may be had from the Medical Department, Boots Pure Drug Co. Ltd., Station Street, Nottingham.

A PANEL ON PEPTIC ULCER

The "Panel Discussion on Peptic Ulcer" at the last meeting of the American Medical Association[1] gives rise to chastening reflections on our ability to treat a disease which, as war enlistment has shown, begins at an earlier age and occurs with greater frequency than we realized four years ago. Duodenal ulcer is our main concern, for duodenal ulcer is both more common and less tractable than gastric ulcer. The patient with duodenal ulcer presents a distinctive pattern, which is localized not only in the duodenum but also in the digestive tract and the constitutional behaviour of the patient. The pattern is characterized by hypersensitivity, hyperirritability, and hyperactivity, which involve both the alimentary tract and the total personality. This psychosomatic make-up tends to run in families. We do not know whether it is inherited or acquired from early influences, but, if acquired, it must be regarded as a reaction formation of the whole personality and therefore unlikely to be amenable to the type of psychotherapy at the disposal of the average physician. Medical treatment is restricted to simple means of relaxing tension, a non-irritating diet, and medicaments to neutralize the corrosive gastric secretion. Owing to the difficulty of controlling the interdigestive secretion, particularly during the long night interval between feeds, the continuous intragastric drip was introduced, with the use of alkaline milk or the newer non-absorbable alkalis such as aluminium hydroxide gel. Winkelstein, who has employed this method for ten years, claims good results in the most resistant cases and has trained hospital patients to carry out the therapy at home. Nevertheless, the most enthusiastic advocate could hardly describe the intragastric drip as either a simple or a permanent cure of peptic ulcer.

The Panel agreed that there was only a limited field for the surgeon in the treatment of peptic ulcer. Operation should be restricted to ulcers which do not respond to routine medical treatment—about 15% of the total. Any procedure that does not remove the pylorus and the duodenal ulcer is inadequate. Gastro-enterostomy is unsuccessful in more than half of the resistant ulcers, and there is a high incidence of jejunal ulceration. The mortality of subtotal resection cannot be reduced much below 5%, and some 10% of the survivors will suffer from post-operative jejunal ulceration or haemorrhage. There are about 20% of recurrences when cases of gastro-enterostomy complicated by jejunal ulcer are treated by gastric resection. Thus a virulent ulcer diathesis can outwit the most painstaking surgery. Kiefer describes these figures as a challenge and an indication for the need for further advance in the surgical treatment of duodenal ulcer. They are an even louder challenge to the research worker. Operation should not be encouraged by the mere suspicion of malignant disease, though American results in the treatment of cancer of the stomach are more favourable than the average physician might have expected from his clinical experience. Walters, Gray, and Priestley[2] report that 10,890 cases of cancer of the stomach were seen at the Mayo Clinic in the period 1907–38 inclusive; 2,322 were fit for resection and survived operation, and of these 28.9% lived 5 years or longer. Thus 7% of the whole series survived 5 years or longer. Recent analysis also indicates that if frank ulcerating carcinomas are excluded, pre-pyloric ulcers are not more often malignant than gastric ulcers elsewhere in the stomach, and the tendency to refer these ulcers at once to surgery should be revised.

In so-called stenosing or obstructing duodenal ulcer, operation should not be advised without preliminary medical treatment, as the changes are usually inflammatory. After control of spasm and oedema and healing of the ulcer, many of these patients may go for years without a recurrence. Operation has little place in the treatment of haematemesis and melaena. The mortality in bleeding peptic ulcer is a direct function of the age. There are few deaths under 45, but thereafter the mortality rises rapidly. Contrary to general belief, more than three-quarters of all fatalities occur after the first haemorrhage, often before there is time to rush the patient to hospital or to institute active treatment. Series of cases for comparison should therefore be arranged in age groups, and not according as the bleeding is single or recurrent. Post-mortem study nearly always shows a large arteriosclerotic eroded artery in the base of the ulcer. Some patients will die whatever treatment is carried out. In a series of cases reported in the discussion conservative medical treatment of bleeding peptic ulcer resulted in a mortality rate of 7.2% irrespective of the age of the patient and the severity of the haemorrhage; among patients with bleeding ulcer treated by resection the total mortality rate was 22.2%. Among patients of 45 and older the medical treatment of peptic ulcer with severe haemorrhage resulted in a mortality rate of 21%; among similar patients treated by resection, the rate was 42.8%. There was no fatality among patients under 45 treated medically for severe haemorrhage, but surgical treatment resulted in a mortality of 30%. The contribution which surgery can make to the treatment of haematemesis and melaena is essentially prophylactic. Two out of every three fatal haemorrhages originate in a gastric ulcer, despite the greater frequency of duodenal ulceration. Post-operative ulceration is almost unknown after resection of the stomach for gastric, as distinct from duodenal, ulcer. There should therefore be no great delay in advising surgical removal of a gastric ulcer which resists medical treatment in a patient over 45. For duodenal ulcer, however, the indications for surgery appear to be limited to perforation, cicatricial obstruction, or persistent pain due to adhesion to a neighbouring viscus.

It has taken the medical profession a long time to learn that neither the dramatic intervention of surgery nor the elaborate ritual of the alkaline diet can banish the constitutional tendency to peptic ulceration. To separate the ulcer patient from his diathesis is like severing the fisherman from his soul, and until we learn some new secret of Nature we must be content to try to teach the patient how best to live at peace with his ulcer—and to do this he must probably learn how to live at peace with himself.

MINIMUM STANDARDS OF FEEDING

It is a brave undertaking of the Economic Intelligence Service of the League of Nations to attempt a survey of rationing in European countries.[1] Even if a super-statistician could accomplish it adequately, a super-publicist would be needed to make the findings comprehensible. Here are more than a score of countries, each with a different kind of rationing system, appertaining to different groups of foodstuffs, and differentiated according to the needs of various groups within each national community. So many qualifications are attached to the tables in which the rations are worked out in terms of grammes per week that the explanatory footnotes, indicated by letters, run nearly twice through the alphabet. Behind it all is the big uncertainty whether legal rationing corresponds to actual consumption. In some countries it is known that large groups of consumers cannot afford to buy their full rations; in others some of the rationed articles are unobtainable. The absence of rationing of certain foodstuffs, such as bread and flour in the United Kingdom, means a genuine lack of restriction, but in others, like the absence of meat rationing in Norway, it means that there is next to nothing to distribute. Milk is still nominally unrationed in Denmark, Sweden, Switzerland, and the Balkans, but this does not necessarily mean that there is no scarcity. Again, who is the "normal consumer"? Consumption varies with age, sex, health, and occupation. The "normal consumer," who represents the minimum standard of adult requirements, must surely be as elusive as the "hypothetical tenant" in the law of estate agency. In parts of Poland under the German heel Jews are not considered to be normal consumers; they are allotted not much more than one-third of the bread, flour, and sugar allowed to the "Aryan." On the whole, the ration card must be held to represent maximum rather than average consumption, even allowing for the fact that, no doubt, many people, by means legitimate or otherwise, are able to supplement their rations. The figures so painstakingly worked out by the compilers of this pamphlet thus furnish only the roughest inventory—and an optimistic one at that—of the bare larders of Europe.

---

[1] *Wartime Rationing and Consumption.* Economic Intelligence Service of the League of Nations. (London: Allen and Unwin, Ltd 3s. 6d.)

Rationing during the last war was worked on the crudest basis. Except for some extra allowance to those engaged in heavy labour, almost all countries distributed food strictly per caput. This time there is a high degree of differentiation. The principle on which rationing is carried out in different countries may be said to follow one of two policies. In the United Kingdom there are basic rations intended to cover the average need of the average family for most of the important articles of food, but these are extended by canteen and municipal feeding schemes and by the priority system for children and mothers in respect of milk. The British method has the advantage of flexibility, though it does mean that some people in favoured situations get more than on a strict apportionment basis they should. The other policy is the much more rigid one which obtains in Germany, where rationing covers almost the entire field of consumption, so that hardly anything can be had without the ration card. This entails an elaborate differentiation between the rations of various occupational and other groups. Thus, while the allowance of bread and cereals, meat, and fats for a normal consumer is reckoned at a little less than 1,200 calories a day, for heavy workers it is 1,900, and for very heavy workers 2,650 calories. To take meat and meat products alone, in Germany the heavy worker receives twice, and the very heavy worker almost three times, the normal consumer's ration. Canteen feeding is organized in Germany, too, but there the workers appear to have to surrender coupons for factory meals. On the whole, the British method seems to be preferable, but here, as in almost all countries, there is some discrimination between classes, and quite a high degree of it in regard to milk for children, for expectant and nursing mothers, and for invalids, which is as it should be.

Some of the results which appear in the tables in this pamphlet are surprising. Thus, apart from Great Britain, Ireland, and Switzerland, where bread and flour are free of coupons and "points," the country of Western Europe with the most abundant bread and flour rations is occupied Denmark, and the country with the sparsest is neutral Spain. Germany lowered her bread ration and introduced potato rationing just a year ago (April, 1942). Until then the level of consumption was apparently maintained, but now some sections of the population may be slightly, though not critically, short of energy-building foods Potato rationing was followed by a decline in bread and cereal consumption of something less than 20% on pre-war figures. In Norway and the Netherlands there has been a fall in these foodstuffs of between 20 and 25%; in Belgium and Czechoslovakia the situation is worse; in Poland and Italy the consumption of bread and cereals is down by one-half or more; and a still more serious state of affairs prevails in Spain, and actual famine in Greece. The consumption of sugar has been cut down most drastically in France and Switzerland. In the United Kingdom the tables show a reduction of about 50% on pre-war figures. In Germany more sugar appears to be consumed, but the pre-war figure for this foodstuff was low. The United Kingdom has the highest meat rations, and Switzerland the next highest; those for Germany and Sweden are only about one-half the British allowance, and in Italy and occupied France the legal ration is much lower. For fats the highest rations in Western Europe are to be found in Denmark, with the United Kingdom and Germany coming next, but the composition of the fats group of foods varies so much from country to country and from period to period that it is useless to seek comparative figures. The milk ration for children under 3 in the United Kingdom is given here as 570 grammes a day, and 750 grammes in Germany, but for older children the British rations exceed the German. The egg ration represents in the United Kingdom 29% of pre-war consumption, and in Germany 17%.

The consumption of foods yielding animal proteins remains relatively high in Denmark, Sweden, and Switzerland, owing mainly to the high consumption of milk; in the United Kingdom, where milk consumption in peacetime was low, it is satisfactory, and in Germany, the Netherlands, and Czechoslovakia it is far below pre-war standards. Total protein consumption, taking the League of Nations standard of optimum allowance,[2] is up to or above that standard in all the countries just mentioned; in France, Belgium, Norway, and Italy it is at minimum level, and in Poland and some countries further east, below it. Serious shortages of vitamin C are reported in Norway, Belgium, the Netherlands, and Poland, and the vitamin A position is unfavourable, though probably not critical, in Germany. The general deduction is that under-nourishment and malnutrition are prevalent in Italy, France, Belgium, Norway, Finland, and Spain, while Poland, Greece, and parts of Yugoslavia, especially Serbia, are in a state of, or bordering on, famine.

That is the broad picture, but to speak in terms of whole countries is highly misleading. A closer picture would show large differences, even within the same country, between urban, semi-rural, and rural communities, and between smaller groups and families. Rationing has not levelled out consumption, even though it has imposed a universal restriction. The important thing is the extent to which it has effected its larger purpose, not merely to limit the consumption of articles of which there is a temporary shortage but to ensure a minimum living standard for the population. Rationing is thought of as a withholding, but ideally it is a form of even-handed distribution which largely ignores individual purchasing power and is based on the physiological needs of the various members of the community. From that point of view the coupon in some form or other may remain as a passport in the post-war world and may be an instrument for ensuring freedom from want.

---

[2] The protein intake for all adults should not be less than 1 gramme of protein per kilogramme of body weight, the protein to be derived from a variety of sources, and a part of it to be of animal origin.

PENICILLIN

Prof. Florey and his collaborators at Oxford have already demonstrated the great potential therapeutic importance of penicillin, an extract from the culture fluid of the mould penicillium. The principal clinical interest of penicillin is, of course, that it will kill certain bacteria, such as *Staph. aureus*, for which there was previously no satisfactory remedy, and (unlike the sulphonamides) even in the presence of pus. Two different lines of investigation have been started as the result of this discovery. First, attempts are being made to purify penicillin itself in the hope that knowledge of its structure will lead to a less laborious and expensive method of preparation than fractionation from the crude extract. Incidentally this should also show how penicillin inhibits bacterial growth. Secondly, the antibacterial activity of large numbers of moulds other than penicillium has been examined with considerable success. According to Florey and his co-workers[1] the crude penicillin extract has a yield of about 4 Oxford units per c.cm. of culture fluid, but by means of absorption, distribution between solvents, and reduction a barium salt has been obtained, with an activity of 450 to 500 units per mg., which appeared homogeneous by chromatographic analysis. By elementary analysis an empirical formula has been suggested for this salt, but its structural formula is necessarily more difficult to ascertain. This purified penicillin completely inhibits the growth of *Staph. aureus* at a dilution of 1 in 24,000,000 to 30,000,000, and is free from toxic reactions as judged by its effect on leucocytes or on mice into which it has been injected. It is very unstable, and is readily inactivated by treatment with acid, alkali, or boiling. In the form of the dried barium salt, however, it keeps its antibacterial power indefinitely.

Among other substances having bactericidal properties and isolated from bacteria or fungi are: pyocyanase from *Pseudomonas aeruginosa*; tyrothricin (gramicidin and tyrocidin), isolated by Dubos and Hotchkiss from *Bacillus brevis*; actinomycin A and B, isolated by Waksman from *A. antibioticus*; and pro-actinomycin. Gardner and Chain[2] were led by their discovery of the last named to investigate a large number of saprophytic actinomycetes, and found that of a total of 52, 10 were bacteriostatic in some degree to the Gram-positive cocci. There is obviously a great deal of work to be done in the classification of these derivatives and the selection of those most suitable for therapeutic trial. Some of them, such as tyrocidin, pro-actinomycin, or claviformin (isolated by Chain, Florey, and Jennings from *Penicillium claviforme*[3]), although their antibacterial activity is high, are unsuitable because they are toxic to mice and stop the movements of leucocytes in high dilution after only a few minutes. The bactericidal activity of such substances is, perhaps, only one expression of a general toxicity to living tissues. Gramicidin,[4] which is now known to be a complex polypeptide and has been crystallized, has limited use in therapeutic trials, for similar reasons. Though much less reactive than tyrocidin, it is relatively insoluble: its antibacterial activity is readily reduced by cephalin, and it is toxic on intravenous injection. However, it is so much less dangerous when applied locally or injected subcutaneously or intramuscularly that it may yet come to be of practical importance. The search among these "bacteriostatics," which will attack the bacterial infection without harming the patient, has already produced a large number having fastidious inclinations—for example, they will inhibit the growth of one strain of staphylococcus without affecting others. Therein may lie future difficulties for the clinician, but the advantages which these new therapeutic substances offer are so great that their future development is clearly a matter of the first importance.

SLOWER NEUTRONS

The destructive action of fast neutrons on living tissue is known to be due to the recoil nuclei, especially hydrogen nuclei, projected by neutron impact; as with *x* rays or gamma rays, the biological effect is a result of absorption of energy by the tissue from charged particles of high energy. In all cases the destructive action occurs throughout the irradiated tissue, but the passage of slow neutrons through the body is not accompanied by the production of such energetic recoil protons, and there is thus little or no resulting damage. Fast neutrons have been used in cancer therapy,[1] but we commented four years ago on the possibility of locally increasing the absorption of energy by neutron-capture reactions with light elements such as boron.[2] Zahl and Cooper,[3] realizing that direct hypodermic injection of slow neutron-capturing materials into tumours was not clinically feasible, substituted lithium for sodium in certain acid dyes which Ludford had shown were selectively absorbed by tumour tissue after intravenous injection. In tumour-bearing mice the concentration of lithium after intravenous injection of lithium-carmine was found to be three times greater in the tumour than in the blood, and in the experiments performed a lithium content of 0.03% was attained in the tumour. This concentration of lithium will capture 10% of the available slow neutrons, and results in an absorption of energy which is nearly three times that in tissues not containing lithium. If the isotope Li^6 is used in place of Li^7 the capture of neutrons goes up to 55%, and the energy absorbed is then more than ten times greater than in tissues not containing lithium. It is not, however, the total energy absorbed but the difference in energy between tumour and healthy tissue which determines the optimum treatment condition. This "dose-differential" depends not only on the difference in the concentration of lithium in the tumour and in the adjacent tissues—the "localization factor"—but also on the absolute quantity of lithium in the tissue, since the "dose-differential" passes through a maximum as the quantity of lithium is increased. So far a localization factor of 2.0 has been attained, giving a gain of 43% in the radiation dosage of the tumour over that of the other tissues; but if the localization factor could be increased to 10 the gain would be 125%.

Zahl and Cooper have so far concerned themselves with establishing the physical and biological facts on which any clinical attempts at therapy with slow neutrons must be based, but they point out that much greater biological effects may be expected than the physically determined dose-differentials would suggest. While the relations between biological damage and density of ionization along the path of a particle are not clearly understood, it seems fairly certain that the biological effectiveness of heavy particle ionization (such as is produced by neutron-capture) is greater than that of electrons (resulting from *x*-ray absorption) by a factor ranging from 2 to 10 or more.

If such a factor is found to apply to the present experiments, the dose-differential of 43% would be considerably increased.

CONTROL OF MOSQUITOES IN BRITAIN

A second and revised edition of the "Memorandum of Measures for the Control of Mosquito Nuisance in Great Britain," with a prefatory note by its Chief Medical Officer, Sir Wilson Jameson, has recently been issued by the Ministry of Health. The authors are Lieut.-Colonel J. A. Sinton, V.C., I.M.S., Adviser on Malaria to the Ministry, and Mr. P. G. Shute, Assistant Malaria Officer, Ministry of Health. Dr. P. G. Stock has been responsible for revising this publication, and in this he has received help from the Keeper of Entomology, British Museum (Natural History). Though the account given in the memorandum of 32 pages, costing 6d., is necessarily concise and condensed, very little of importance in connexion with the mosquitoes of Great Britain and their habits and methods of control is omitted. The memorandum will be found a most useful source of knowledge by those whose interests or responsibilities bring them into touch with this aspect of the public health. In addition to what was given in the previous edition (1940), the present one provides some new and useful information on the control of mosquito breeding in static water tanks. There has also been added a short appendix, giving some notes on other biting flies than mosquitoes which may at times be troublesome in this country. We have already commented, when reviewing the first edition,[1] on the fact that, besides the common house mosquito, *Culex pipiens*, which breeds mostly in outdoor water butts and other open collections of water, and which incidentally rarely bites man, there is a very similar-looking species, *Culex molestus*, only recently recognized as distinct from *C. pipiens*, which bites man freely. *C. molestus*, it now appears, selects as its breeding places water which is in continuous darkness or semi-darkness, and has so far not been found, according to the memorandum, in static water tanks above ground. Larvae, however, are to be found everywhere in the stagnant water in the inverts below the station platforms of the Underground railways and in sumps along the railway line. It does not follow, however, that the mature insects do not occur above ground, and they may be a source of nuisance in houses in urban areas. Other species of culicine mosquito occur and may be troublesome under rural and semi-rural conditions, and such species are briefly described, with their habits and breeding places. More important than the culicine mosquitoes, since they may be actual carriers of disease, even in this country, are mosquitoes of the genus *Anopheles*. One variety—that known as the *atroparvus* variety of the common *A. maculipennis*—is the cause of indigenously contracted malaria, especially under war conditions, when many soldiers and others returning from abroad provide the necessary sources of infection. During the last war some 500 cases of malaria proved on investigation to have been locally contracted in this country. In the text of the memorandum are two very interesting maps comparing the distribution of malaria in England in the eighteenth century, when, under the name of ague, malaria was relatively common, with that of indigenously contracted cases recorded during and after the last war. The areas—chiefly south of the Humber, in an extensive area about the Wash, on the Essex coast, in the Thames valley, and in parts of Kent—are almost identical. It is in these areas that local bodies and medical men should be particularly alive to the possibility of locally transmitted malaria and the importance of taking such precautions as are desirable.

SIDE-TRACKING THE LIVER

New methods of administering drugs are always of interest, and modern therapeutic requirements, which postulate the slow, steady liberation of a substance within the body over a period of months or even years, as in pernicious anaemia, Addison's disease, and other hormonal dyscrasias, have led to a number of ingenious devices. Thus "replacement therapy" may be attempted by the implantation of tablets subcutaneously or by the injection of an oily solution from which the active substance is slowly liberated. The patient with myxoedema is fortunate because the missing substance is not destroyed during digestion, but the diabetic must resign himself to his daily injection. Sublingual therapy—the absorption of a drug from a tablet which is placed beneath the tongue and is slowly dissolved in up to half an hour—has the advantage that it is simple and not unpleasant for the patient. Though still mainly in the experimental stage, it has already been found useful in the treatment of Addison's disease. While there is reason to believe that desoxycorticosterone acetate is not as efficient as the crude extract of the adrenal cortex, sublingual administration has proved valuable in patients whose condition has become stabilized, and who can be discharged on a diet and maintenance dose.[1]

Sublingual therapy is now being tried with some success with the sex hormones. It is well known that many of these compounds (except, of course, synthetic analogues such as stilboestrol) are relatively ineffective by mouth. But, as Miescher and Gasche[2] have shown, alcoholic solutions of testosterone, methyl testosterone, and oestradiol are far more effective in encouraging the growth of the secondary sexual characteristics in castrate albino rats when administered sublingually than when given by stomach tube. It has been suggested that this difference is due, not to inactivation by digestive juices or failure of absorption, but to inactivation of these compounds as they pass by the portal circulation from the intestines through the liver. Burrill and Greene[3] found that testosterone and methyl testosterone were very active when implanted subcutaneously in castrate rats, as judged by the increase in weight of prostate and seminal vesicles over castrate controls. When the pellets were implanted in the spleen, so that the androgens were carried directly to the liver on absorption, methyl testosterone still had a little effect but testosterone was completely ineffective. (Even when orally administered methyl testosterone is active to some extent, so perhaps the methyl side-group may delay its destruction by the liver.) If the liver naturally detoxicates these sterols sublingual administration will side-track the liver, and the sterol will be absorbed directly into the peripheral blood stream. Spence[4] has already detected this difference clinically, for in the case of a eunuch sublingual administration daily of two tablets of 5 mg. each was sufficient to maintain normal potency, whereas when the substance was swallowed three such tablets were required. This side-tracking of the liver is an unusual advantage to be claimed for any method of treatment, but there is evidently sufficient value in sublingual therapy for an extensive trial.

Sir Henry Dale, P.R.S., has been awarded the Harben gold medal by the executive committee of the council of the Royal Institute of Public Health and Hygiene. This medal, which is international in character, was instituted in 1894 and is conferred every third year for "eminent services rendered to the public health."

MILITARY ORTHOPAEDICS

At a special meeting of the British Orthopaedic Association, held in London under the presidency of Mr. G. R. GIRDLESTONE of Oxford, Lieut.-Col. St. J. D. BUXTON, after first describing the organization of the orthopaedic service in the Middle East, went on to discuss the clinical work done out there. Primary suture of wounds, he said, especially those complicated by fracture, was to be avoided in the Western Desert. Foreign bodies should not necessarily be removed at forward operating centres. When amputation was carried out in the forward area the stump should be dressed with sulphanilamide powder and a loose vaseline gauze pack. A stitch or two might serve a useful purpose, but closure of the wound was to be condemned. If a wound was packed in a forward area, care must be taken that this packing was loose and did not act as a plug. There was ample evidence that limitation of change of dressings and the use of plaster-of-Paris splinting were an advance in the treatment of gunshot wounds of the limbs. Out of 200 cases of gunshot wounds causing fracture of the femur deaths at the base numbered 13, and amputations also 13. Of 273 wounds of the knee-joint 178 were non-suppurative and 95 suppurative; five patients died from various causes and 12 amputations were carried out. Of 51 wounds of the elbow-joint 12 were complicated by injury to one or more nerves; two arms were amputated; no death was directly due to the lesion of the joint.

Col. E. C. CUTLER, U.S. Army Medical Corps, emphasized that there was no place in the forward areas for the limited specialist; men there should have had adequate general surgical training. He emphasized the value and probable importance of air transport for the wounded in modern campaigns, so that cases requiring special treatment could at an early date be evacuated to the general hospitals where full orthopaedic facilities were available. In his view, orthopaedics had an important part to play in the application of its principles to the problems of trauma: lessons which could well be carried back to the medical schools and the benefit ultimately of civil practice.

Finger Injuries in Tank Crews

Major FURLONG, discussing four "minor" injuries, dealt first with a type of finger injury commonly seen in tank crews—a crushing of the tip of one or more digits by the sudden closure of roof-flaps. He emphasized the need for conservatism in regard to end-tissues, and described satisfactory results obtained by covering the ends of the fingers by whole-thickness skin grafts, with loose dressings to avoid rigid immobilization and consequent stiffness. In fractures of the metacarpals the surgeon should regard the injury as a contusion of the hand rather than a fracture, and so should pay attention to the restoration of function in soft tissues rather than to splintage. Return to duty after Bennett's fracture was quicker and more satisfactory if reduction was not attempted. For fractures of the clavicle he advocated auto-reduction by the soldier employing the "hips-firm-shoulders-braced-back" attitude, during which a figure-of-eight bandage should be applied over both shoulders without padding. The patient's whole effort should then be to maintain the position actively. Early movements and return to light duty with his unit at the end of three weeks were the rule.

In a paper on the surgical treatment of osteomyelitis the result of penetrating wounds, Major G. PERKINS said the osteomyelitis pursued one of five courses: (*a*) the inflammation might resolve and never again trouble the patient; (*b*) it might continue as persistent acute osteomyelitis; (*c*) the acute inflammation might subside leaving a sinus down to the interior of the bone; (*d*) it might heal but after months or years might recur—the wound had flared; (*e*) there might be a persistent sinus associated with recurrent "flares" of acute inflammation in the bone. In persistent acute osteomyelitis surgery was rarely necessary to cure the inflammation; drainage because of the wound was usually adequate. Later amputation might be advisable, either to save life or because an artificial limb would be of more use to the patient than his own crippled leg in cases with an ununited fracture or serious nerve lesions which could not be sutured, or soft-tissue loss. In the next group of cases the sinus might remain (1) because of the presence of a foreign body or sequestrum, or (2) because of continuation of mild chronic infection of the bone. In (1) the cavity should be exposed carefully without excision of the track which had been opened up, dead fragments should be removed, followed by light suture without drainage. Careful judgment was required because sequestra and foreign bodies were not always revealed radiographically, and also because of the difficulty in deciding when inflammation had sufficiently subsided to permit such interference. When operating for continued infection without sequestra the procedure was different as the object was to remove all infected bone. This, of course, might not be entirely practicable. Here the obliteration of cavities was important; no more than half the circumference of the infected bone should be chiselled away, care being taken not to fracture the bone. The immediate sequel was acute inflammation of the bone that was left; therefore there must be free drainage by light packing with paraffin-soaked gauze, which should be removed as soon as a "safety valve" was no longer needed. Major Perkins emphasized the need for conservatism in recurrent attacks of acute osteomyelitis, the essential treatment being rest; surgery was not indicated unless an abscess formed, and then only an exit for pus was necessary. Cases in which there was a sinus associated with recurrent flares as a rule defied treatment; usually there was a continuous grumbling inflammation in a bone that was riddled with organisms. The more serious cases in the lower extremity amply justified amputation, which first should be done through the lowest limit of healthy bone. When all sepsis had been eliminated the final amputation was done at the site of election.

Knee-joint Injuries

Major T. T. STAMM, discussing injuries to the knee-joint, said that in civil practice the operation for the removal of a torn semilunar cartilage had always been regarded as one of the most satisfactory of all surgical procedures. Those who had had the opportunity of dealing with large numbers of troops would agree that in general the results of this operation in the soldier were most disappointing. The men themselves had come to regard it with increasing suspicion, and not without reason, having observed bad or indifferent results among their fellows. Bad results following surgery were doubly unfortunate in the Army, for not only did they render the individuals concerned inefficient fighting units but they might cause others to refuse operation when they could have been cured. Inexpert operative technique was rarely the cause of these poor results, which could usually be traced to inaccurate diagnosis or mistaken judgment in immediate or post-operative treatment. He stressed the need in diagnosis for examination of the joint under intravenous anaesthesia. The injury most often missed was a lesion of the anterior cruciate ligament, which was probably the commonest of the injuries sustained by the knee. It might be the only lesion present, and in such cases it was nearly always possible to lock the joint and unlock it while performing a diagnostic test which had been elaborated by Mr. Lambrinudi. All degrees of damage to the ligament were encountered, from a simple sprain to a complete rupture. It was in cases with minor degrees of damage that mistakes might result, since the knee was held flexed by spasm of the hamstrings, which might be mistaken for locking of the joint. In late cases there were two groups of symptoms: first, those due to the lesion itself—a feeling of insecurity and of the knee "coming forward" suddenly when under load in the semiflexed position: there was no actual locking; secondly, those due to slipping of one or other cartilage, usually the medial: momentary locking was the main feature. In spite of the symptoms, no lesion of the cartilage would be found at operation. While operation might be justified in a few selected cases where repeated attacks of locking caused severe disablement, as a general rule it should be avoided, as the results were not good and did not permit the individual to be up-graded.

Discussing true cartilage tears Major Stamm emphasized the importance of differentiating between tears of the substance of the cartilage and peripheral detachments of the cartilage from the capsule. The former occurring in the non-vascular material produced less reaction but did not heal. In the latter the reaction (haemarthrosis, tenderness, etc.) would be severe, because of the vascularity and sensitivity. Paradoxically, therefore, those injuries which appeared more severe did best with conservative treatment and healed as well as any other.

In the apparently less severe cartilage lesions operation would more often be necessary. Major-General **Munro** and Prof. **Harry Platt** emphasized the need for thorough investigation by medical officers at the time of the first injury, when details of the mechanism involved could be ascertained, the nature of the lesion determined with accuracy, and correct prognosis given. Major **Stamm** agreed that patients with internal derangement of the knee should be treated like fracture cases and sent to hospital at once.

The need for early, accurate diagnosis was stressed in a discussion of another common injury—namely, fractures of the carpal scaphoid. Major G. D. **Rowley**, reviewing 450 cases, said difficulties were experienced not only because of delay in diagnosis but because of imperfect suspension and immobilization. In fractures occurring in the proximal third and those with displacement of fragments the prognosis appeared to be poor. It seemed questionable whether a graft was ever justifiable in a private soldier. A certain number of delayed unions would unite if immobilized over a long enough period. For recent strains in old-standing lesions plaster immobilization for four to five weeks would often relieve symptoms. If there was not a perfect result a soldier would have difficulty in handling a rifle or ammunition as a member of a gun crew. These facts must be considered when advising treatment or in making recommendations for medical category.

Mr. C. **Lambrinudi** brought forward important new evidence concerning the mechanics of the carpal joints in relation to displacement of the scaphoid fragments, which he showed to be associated with a minor degree of subluxation of the lunate bone The "cystic" appearance seen in some fractures of the scaphoid was due to "opening" up of the fracture gap. He stressed the need for accurate reduction of all scaphoid fractures and of the intercarpal subluxation before the application of plaster fixation. Major **Soto-Hall** of the U.S. Army Medical Corps also emphasized this and the method of impaction to be achieved by a manœuvre which he demonstrated. In fractures of the right scaphoid the surgeon's left hand provided counter-pressure against the lower end of the humerus with the elbow flexed, while pressure was exerted by the first interosseous space of his right hand against the interosseous aspect of the patient's first metacarpal, whose wrist was forced into slight dorsiflexion and radial abduction—plaster being applied in this position and including the interphalangeal joint of the thumb. Over 90% of perfect results should thus be obtained.

Future Civil Accident Services

During the meeting Mr. R. **Watson-Jones** presented a report on behalf of the executive committee dealing with the future of accident services, which was approved by the association.

1. The B.M.A. Fracture Committee in 1935 and the Delevingne Committee in 1939 recommended the development of special fracture services based on the principles of segregation of cases and continuity of treatment and after-care under a unified control.

2. The comprehensive accident service of the future is a natural development of organized fracture services which was foreshadowed by the B.M.A. and Delevingne reports It should embrace the treatment of soft-tissue injuries, infections of the hand, burns, tendon injuries, nerve injuries, and indeed all injuries of the locomotor system. These injuries are no less incapacitating than fractures, their importance to industry is just as great, and numerically they outnumber fractures in the proportion of five or ten to one.

3. In general the problem will be solved more readily by the reorganization of accident departments of general hospitals than by the formation of special accident hospitals. The accident department must be reorganized, replanned, and often rebuilt. There must be a separate organization, and even a separate door of entry for accident cases on the one hand and acute medical and surgical emergencies on the other.

4. The director of the accident service should be a surgeon who is first trained in every branch of surgery, is then experienced in orthopaedic surgery, and is specially trained in the problems of trauma. He will collaborate with surgical colleagues who treat visceral injuries, and with physicians, bacteriologists, and representatives of other special branches of medicine.

5. It would be very inadvisable to propose the development of a new branch of surgery—"traumatology"; or to train "traumatic surgeons" whose skill would be disseminated over the vast fields of locomotor, abdominal, thoracic, facio-maxillary, ophthalmic, and cerebral surgery.

6. Since the accident unit must provide a twenty-four-hour service, it is considered essential that the director should be aided by two first assistants, in addition to the usual resident surgical officers, house-surgeons, and house-physicians. There must be full secretarial and clerical assistance, and almoners or social service personnel. A close liaison must be established with industrial medical officers in the area served by the accident unit

7. The rehabilitation of sedentary and light industrial workers can usually be completed within the hospital itself by physiotherapy, occupational therapy, and recreational therapy; but for the rehabilitation of more seriously injured patients who must return to heavy industry the accident service must have a special rehabilitation annexe with playing fields, swimming pools, and gymnasiums. Such special centres are essentially medical units where treatment is continued by the same team, and they must remain under the same administration and surgical control as the parent hospital

COMMITTEE ON NUTRITION SURVEYS

Investigation on certain aspects of nutrition is at present handicapped by lack of co-operation. Investigators may be ignorant of other work similar or related to their own; they may have difficulty in finding others who could co-operate in making their work complete; they may use different methods, the results of which are not comparable. The most striking example is that of estimations of haemoglobin levels, which have been made by a variety of methods, some of which are by no means satisfactory. In this particular case the Medical Research Council has set up a committee with the object of co-ordinating surveys of haemoglobin levels and some other blood examinations.

There remains, however, a wide field that is not covered by any existing organization. In view of the importance, at the present time, of a thorough knowledge of the state of nutrition in the country, the Nutrition Society has set up a committee on Nutrition Surveys, with Sir Joseph Barcroft as chairman. The terms of reference are the co-ordination of nutrition surveys dependent on (*a*) clinical, physiological, and biochemical examinations of human subjects; (*b*) examinations of food budgets; and (*c*) chemical analyses of food and meals (including collective meals). It will put investigators in touch with others who are working on the same lines or would co-operate; it will supply information, recommend methods, and make periodical summaries of the results of investigations. The committee has the support of the Ministries of Health and of Food and the co-operation of the Services. Prof. J. R. Marrack has been appointed as a director serving under the committee. All who are engaged on or undertaking investigations covered by the terms of reference are invited to communicate with him at the London Hospital, Whitechapel, London, E.1.

Reports of Societies

SULPHONAMIDE THERAPY

At a meeting of the Fever Hospital Medical Service Group of the Society of Medical Officers of Health a discussion on chemotherapy was opened by Dr. B. **Barling** (L.C.C.), who, after tracing the development of the sulphonamide group of drugs, pointed out that hundreds of preparations had now been synthesized but only some six were in common use in this country. An effective blood concentration of 3 to 15 mg. % depended on (*a*) regular intake of the drug and (*b*) the output of urine. During treatment sulphonamide was found in all normal tissues except fat and compact bone and in all normal and pathological body fluids. Most drugs in the group passed into the cerebrospinal fluid, some more readily than others.

In discussing the mode of action of the sulphonamides, Dr. Barling pointed out that their bacteriostatic action could be blocked by para-amino-benzoic acid or substances clinically allied thereto, which included a number of local anaesthetics in common use. In this way sulphonamide might be rendered virtually inert. Large-scale experiments in gonococcal cases showed that sulphonamide resistance could appear as (*a*) an absolute resistance, (*b*) a relative resistance, or (*c*) an acquired resistance due to the use of too small a dose. This last, he felt, was a real danger which was not new to chemotherapy; it already had been often encountered in the specific treatment of trypanosomiasis. Dosage, therefore, must be adequate, and he suggested 1 gramme of sulphonamide for every 20 lb. of body weight in an adult; this amount to be multiplied by two in the case of children and by four in infants. The total amount thus obtained should be divided so as to administer the drug at regular four-hourly intervals throughout the twenty-four hours. Given adequate dosage, the next important step was to choose a preparation of the drug to which the infecting organism was known to be sensitive. If no obvious response was obtained it was quite wrong to persist with the drug for longer than 7 to 10 days. Another common fault was to attempt sulphonamide therapy of deep abscesses or infected wounds without preliminary surgical treatment.

Chemotherapy in Pneumonia

Dr. THOMAS ANDERSON (Glasgow) thought it could be assumed that the value of chemotherapy in pneumonia had been proved, but there were important aspects of the results of chemotherapy which might be discussed. Pneumococcal pneumonias generally, for example, showed a considerable variation in severity and mortality when treated with sulphonamides, depending on the serological type involved. The results of chemotherapy in Glasgow, where the commonest type of pneumococcus has been Type II, were much less impressive than in the South of England, where the more benign Type I infection was prevalent. The results in Type III infections varied principally with the age of the patient. During 1939-40 and in the early part of 1941 Type III cases were predominantly among the older age groups and carried a high fatality rate. Since then, among younger persons, Type III cases had been much milder. Age appeared to be of increasing importance in assessing results obtained by chemotherapy in pneumonia. Taking Type II infections alone, he found that the fatality rate in persons under 40 years had fallen as a result of chemotherapy from 22 to 4%, whereas in the older age groups the fall was from 46 to 25%. Further, an analysis of 69 consecutive pneumonia deaths in cases treated by chemotherapy showed that 81% were in persons over 40 years of age. Bacteriaemia was another important factor in determining the outcome of an attack of pneumonia, and there was some reason for believing that the risk of bacteriaemia increased with age. The relative failure of chemotherapy in those over 40 with bacteriaemia was probably due more to the impoverished defences of the host which permitted bacteriaemia than to the presence of the organism itself in the blood stream. One of the most disturbing features about pneumonia cases treated by chemotherapy was the prolongation of convalescence by delayed resolution. The incidence of this was again greatest in those over 40 years and in those with bacteriaemia, which also appeared attributable to lack of tissue resistance.

Generally, Dr. Anderson felt that the introduction of the sulphonamides had not removed pneumonia from that group of diseases which required intensive study. Could the factors described, which influence the outcome, be related to treatment? He was not convinced that better results could be obtained in the "bad risk" groups by increasing the dose of the drug, and there was no evidence that the drug was less well absorbed by persons in the older age groups. Combined treatment with chemotherapy and serotherapy, using specific serum, produced no better results as judged by fatality and delayed resolution than chemotherapy alone. Nor did vaccines as an adjuvant appear to influence the course of the disease. In conclusion, he suggested that the lack of specificity of drugs of the sulphonamide group, which were effective against a wide variety of organisms, argued in favour of the view that the drug acted principally by rendering the organism more susceptible to the natural defences of the host. That being so, tissue resistance was a more important factor in promoting recovery from and resolution of pneumonia than the presence of specific antibodies or neutralizing substances.

Meningococcal Infections

Dr. H. STANLEY BANKS (L.C.C.) considered sulphathiazole the drug of first choice for meningococcal infections. Comparing 200 cases treated with sulphapyridine with 300 treated with sulphathiazole he found the latter drug apparently more potent and much better tolerated. The use of this drug or sulphadiazine made all the difference to the comfort of the patients. Supplies of sulphathiazole had recently improved and were soon likely to be generally available. The cost at present was about double that of sulphapyridine, but with increasing demand should soon be reduced. Sulphadiazine was the drug of second choice, but at present was very expensive and had to be imported. As a practical compromise, until supplies were normal, all but the most severe cases could be treated with one or the other of these drugs for the first three or four days and the course completed with sulphanilamide. A standard of dosage based on body weight was fallacious if applied to all ages. Infants excreted the drugs rapidly and required 2 to 3 times the adult standard in proportion to body weight. No infant should be given less than 3 grammes daily during the first two days of treatment. For adults during this period 9 grammes daily was an appropriate dose, and for children an intermediate amount according to age. The mortality had been greatly reduced by chemotherapy. In 1940 and 1941 approximately 20% of notified cases died, compared with about 60% in pre-sulphonamide years. Judging by certain large series of hospital cases in which the case-fatality rate was as low as 6 to 8%, he thought that the mortality of this disease in the country generally could be still further improved. The chief types in which a high fatality rate was unavoidable were those (1) with adrenal involvement, (2) with encephalitis, (3) with ordinary meningitis undiagnosed and untreated till a late stage. Age should be only a secondary factor in fatality. Quite low fatality rates in infancy and over the age of 45 years had been achieved.

Acute Gastro-intestinal Disorders

Dr. W. GUNN (L.C.C.) classified acute gastro-intestinal disorders into three categories: (1) enteral causes due to specific organisms; (2) parenteral causes in which the intestinal upset is due to a focus elsewhere, frequently the upper respiratory tract; (3) causation unknown, commonly called acute gastro-enteritis or infective enteritis, but numerous designations had been employed at different times. Routine use of highly enriched or selective media (desoxycholate citrate agar for dysentery-salmonella group and Wilson Blair media and tetrathionate broth for enteric group) and rectal swabs as well as faeces had greatly improved diagnosis in the last few years. The employment of sulphaguanidine (3 grammes t.d.s. for 3 days and b.d. for 4 days, making a total of 51 grammes in 7 days) in 23 cases of Flexner dysentery resulted in more rapid clinical recovery (diarrhoea 2.6 days against 5.8 days) and elimination of organisms (6.8 days compared with 15.1 days) than in an approximately equal number of controls observed at the same time. No such beneficial effect was observed in 7 cases of salmonella (Thompson) food-poisoning and 7 carriers compared with controls. The total admissions of acute gastro-enteritis to a fever hospital during 1942 were analysed; the case fatality of unselected cases was 20.3%, but in the severe group accompanied by dehydration it rose to about 50%; of 22 severe cases treated with succinyl sulphathiazole or sulphasuxidine (supplied from the M.R.C. through the courtesy of Sir Henry Dale) 12 died. The case fatality was 45.5%. The rationale of the treatment was a reduction or elimination of coliform organisms allowing earlier oral administration of sugar than was possible without the drug. The verdict on the measure must for the present remain one of not proven.

Sulphonamides in Measles

Dr. R. SWYER (L.C.C.) recorded the results of an experiment carried out with sulphanilamide and sulphapyridine during the 1940-1 measles epidemic. One or other drug was administered for a period of four days after admission to 324 children suffering from measles. A further 869 children were observed as controls. No significant effect could be demonstrated either on the initial phase of the measles attack or on the incidence of complications. He felt, therefore, that the indiscriminate use of these rather toxic drugs could not be justified prophylactically in measles. Used therapeutically for certain complications, the results were better; the complications most likely to benefit being those due to streptococci or pneumococci, particularly bronchopneumonia. The fatality rate among measles-pneumonia cases treated with sulphonamides was 11.2%, compared with a 30% mortality experienced in a pre-sulphonamide epidemic. The results of chemotherapy in established measles-otorrhoea were less satisfactory, but he felt that his series was too small for any definite conclusion to be drawn. There was a danger, he thought, in using sulphonamides in the early stage of otitis media, unless the patient was under expert and continuous observation, because the symptoms of onset of mastoiditis could be masked thereby.

PSEUDOHERMAPHRODITISM

At a recent meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland Dr. EDWARD SOLOMONS reported a case of pseudohermaphroditism due to hyperplasia of both adrenals. The patient, aged 18 years, had never menstruated and was suffering from generalized hirsutism and had a very enlarged clitoris. There was no vagina and the breasts were undeveloped. Laparotomy revealed the presence of underdeveloped female internal genital organs. The adrenals were symmetrically enlarged. The only other noteworthy feature was the urinary excretion of enormous amounts of 17-ketosteroids.

Dr. O'DONNEL BROWNE said he had a patient, aged 22, who had never menstruated and was probably a case of pseudohermaphroditism. She had definite ovaries, no testicles, no vagina, well-marked clitoris, and good distribution of hair Findings were identical with those of Dr. Solomons's case. On laparotomy definite enlargement of both adrenals was found, in particular in one. Mr. Gill tried to remove what could be removed of the adrenals. Examination of the specimen showed that the tissue which was removed was malignant. The ultimate result he could not tell as it was too recent to report fully.

Correspondence

Gastro-enteritis in Infants

SIR,—After reading the interesting article by Drs. Elaine Field, D. MacCarthy, and W. G. Wyllie (March 27, p. 371), I turned up our records to find that, barring Sonne dysentery and enteritis complicating fevers, we have in the past eight months treated for "gastro-," "infective," or "zymotic" enteritis 146 children under 2 years of age with 21 deaths. Of course no comparison with the Great Ormond Street group is possible or intended. Our series was more heterogeneous, nor do I doubt that it was diluted with a number of instances milder than any of those dealt with in the article; still we did encounter very severe cases, including many with the deadly coffee-ground vomit and occasionally even frank haematemesis (three only recovered; but what is the cause of this evil symptom?).

The point I should like to see stressed is the importance of the nurse in the management of these cases. A ward full of such infants imposes a great strain on the whole staff, but a skilled and conscientious sister can work wonders with most unpromising material. Our medication was simpler and less systematized than that of the G.O.S. series, relying more on simple subcutaneous infusion, less on intravenous drip. Some did receive intravenous infusions on the lines laid down in the article, but none benefited, for all treated in this manner died ultimately of starvation. Another point is the use of Benger's food when restoring the starved babies to a milk diet. No mention is made of this product in the article, though our most experienced nurses swear by it. At the very least our results are no worse than anyone else's.

It is worth noting that the majority of our cases were admitted directly from their homes, for here is another point of some public importance. On several occasions the arrival in hospital of a sick baby has been quickly followed by the appearance of enraged parents accusing some day nursery, residential home, hospital, or what-not of poisoning their child, of incompetence, of neglect, etc.

Now anyone experienced in this disease knows that infection of the milk has little or nothing to do with the matter; indeed, when a recognized pathogen is found in stool or vomit the prognosis is thereby improved. Our cases were uniformly negative. Though doubtless, in the words of Jeremy Taylor, "we long for perishing meats, and fill our stomachs with corruption" (for how could we digest the incorruptible?), in this condition surely some more volatile essence, probably a virus, must be sought. In many of our cases there seemed to be a well-defined prodromal period, followed in three or four days by a rise of temperature and an exacerbation of symptoms suggesting that we are dealing with an acute fever. And the toxicity—that "flat-outness" with eyes wide open as though staring at some devil—is in strong contrast to the remarkably negative post-mortem appearances. Where, you ask yourself, is the "gastro-enteritis" which killed this baby? Moreover, has not the severity of this mysterious "gastro-enteritis" in recent months marched cheek by jowl with an influenza-like disorder in adults and older children? I think it has. At any rate here is an illness quite other than the old-fashioned "summer diarrhoea" of infants, and one not likely to be overcome by anything less than a great combined operation.—I am, etc.,

The Grove Hospital, Tooting. J. B. ELLISON, M.D.

SIR,—The apparent success in the treatment of infantile gastro-enteritis with sulphaguanidine reported by Dr. J. L. Henderson (April 3, p. 410) is encouraging, but it is unfortunate that his clinical experiment was inadequately controlled. As we have already explained (March 27, p. 371) the mortality from this disease depends to a large extent on the severity of the infection. This varies enormously in different epidemics. It is difficult to estimate accurately the severity of the disease therefore it is most important when assessing the value of an individual treatment to use an equal number of controls, preferably only giving alternate cases the specific remedy, the remainder of the treatment being standardized. Only under these conditions can a comparative assessment of various treatments be formulated and ultimate progress in the prophylaxis and treatment of gastro-enteritis be made.—We are, etc.,

C. ELAINE FIELD.

Flavines as Surface Antiseptics: Influence on Healing

SIR,—We regret that Prof. C. H. Browning should have concluded his opportune review of the aminoacridines (flavines) as surface antiseptics (March 20, p. 341) by authoritatively perpetuating the opinion that "retardation of granulation and healing tends to follow continued use of the flavines"; and this despite and contrary to the cited findings of his co-workers (1922). He also states that "Bennett did not experience it in over 600 cases. In tissues from this series Blacklock found mitoses of various cell types at levels of 1/50 to 1/5 mm. below the actual growing surface."

This prompts us briefly to restate here our conclusions *qua* proflavine and the rate of healing, based on our observations and measurements during the last three years on the continuous use of depots of proflavine in occlusive emollient dressings for treating infected granulating areas—burns (*Lancet*, 1942, **2,** 527). These depot dressings permit of a free and steady diffusion of antiseptic dyestuff in optimum and slowly diminishing amount, and replace entirely the useless *B.P.C.* acriflavine emulsion, in the cera alba of which the acriflavine is almost completely immobilized (*Lancet*, 1942, **1,** 347). The initial concentration of proflavine yielded by the depot dressing is about 1/500, slightly more than half the maximum concentration in serum, 1/300, obtaining in the wounds treated by Mitchell and Buttle, who used proflavine powder; the concentration available from depot dressings after 4 to 8 days' application varies from 1/5,000 to 1/20,000 and 1/2,000 to 1/4,000, according as the proflavine is in the water phase of a buffered (pH 6.2) isotonic oil-in-water emulsion or in an oily preparation of proflavine oleate in liquid paraffin and petroleum jelly (*Lancet*, 1942, **1,** 347; 1943, **1,** 159).

Using these depot dressings for infected granulating 2nd and 3rd degree burns and changing them at intervals of 4 to 8 days:

1. "All cases treated with proflavine sulphate have healed within what are to be regarded as 'normal limits'—that is, within average times ascertained from parallel observations and measurements in comparable, non-infected cases of burns treated by tannic acid and gentian violet coagulation methods."

2nd-degree Burns of Foot and Leg

Non-infected Control.—Tannic acid "tan" separated 30th day Area burned 367 sq. cm. Overall rate of healing (injury—epithelization): 0.815 sq. mm. per mm. circumference per day.

Infected Case.—Area 431 sq cm. Epithelized 26th day. Proflavine-urea o/w emulsion 19 days, 4 changes, Overall rate of healing 0.85 sq. mm. per mm. circumference per day (injury—epithelization, including infected period).

2. Proflavine does not inhibit fibroblastic activity and epithelization in the healing of large granulating areas where the rate of healing is great. Thus in areas of the size of a sheet of foolscap paper, when infection is terminated by proflavine, the healing edge

may advance inwards at the remarkable rate of 0.5 cm. per day, *under continued proflavine applications.*

2nd-degree Burns of Arm and Forearm (Infected)

A.—Area 636 sq. cm. Epithelized 26th day from injury. Proflavine–urea o/w emulsion 14 days, 3 changes. Rate: 5 sq. mm. per mm. circumference per day.

B.—Area 534 sq. cm. Epithelized 32nd day from injury. Proflavine oleate–petroleum jelly 27 days, 4 changes. Rate: 4.2 sq. mm. per mm. circumference per day

3. Proflavine sulphate has no inhibitory influence on fibroblastic activity in exuberant granulations resulting from simultaneous hyperosmotic action of urea 5%. Thus in Case 5 (*Lancet*, 1942, **1**, 347) granulations were exuberant even in the 6th week of application of proflavine–urea emulsion.

All our dressings have been of an emollient nature and changed only at intervals of 4 to 8 days or longer. This is essential for the preservation of recently healed tissue. The daily or twice-daily changing of wet dressings become dried destroys newly formed tissue and delays healing If such wet dressings must be employed in granulating wounds they should be wetted with warm normal saline before removal. As well as preserving new-grown tissue, this minimizes the air-borne dissemination of organisms from exudate in the wound and in the dressings (unpublished work).

We would add that our experience is in agreement with Prof. Browning's final point on the capacity of flavines in practice to prevent or control infection, for while one initial treatment with acriflavine 1/1,000 may prevent infection in burns treated with tannic acid for 2 to 7 days, as compared with 5 to 10 days after mercury perchloride 1/5,000 (*Lancet*, 1942, **2**, 664), proflavine depot dressings have completed and maintained the sterility of granulating areas moderately infected previously. This experience led us to commend the use of proflavine depot dressings in first-aid measures for the numerous 2nd-degree burns of mobile warfare, to cover the 2- to 4-day period of evacuation, and thus prevent the high (90%) incidence of infection and the consequent delay in healing in such casualties (*Lancet*, 1943, **1**, 159).—We are, etc.,

J. F. HEGGIE.

Vitamins and Physical Efficiency

SIR,—In his letter (March 27, p. 394) dealing with the subject of our paper Sir Adolphe Abrahams stresses the difference between his experience and ours. We are not surprised at this. (1) The subjects we dealt with were healthy young men already selected by the Services after making their own tests. They were not record-breaking athletes, highly trained for some particular test of athletic performance. (2) Sir Adolphe quotes only "general experience" as his evidence, whereas we think it clear from our results that the differences we observed in the two groups with and without vitamin supplements would have been revealed only by careful statistical examination.

The R.A.F. breath-holding and endurance tests are designed not to measure ability to perform specialized muscular exercise but to afford indications of the stability of the respiratory and circulatory centres and the resolution and general power of endurance of the subject (H. G. Armstrong, *Principles and Practice of Aviation Medicine*, p. 47). Sir Adolphe expresses dissatisfaction with the records of these tests in our paper on the ground that our subjects averaged practically a minute in the endurance test at their first examination, whereas he has no record of any man exceeding 50 seconds in this test, and has examined athletes who "faded out at 20 to 25 seconds." Since "the average time in a large number of cases tested is between 50 and 60 seconds" (Wing Cmdr. T. S. Rippon, *British Encyclopaedia of Medical Practice*, **2**, 229), it would seem that it is Sir Adolphe's rather than our results which require justification and explanation.

We should like to stress that on the basis of our work we could not recommend the administration of vitamins to all would-be champions in the hope that they may become real ones. That achievement depends on many other things besides the general state of nutrition. Finally, Sir Adolphe is not able to accept the significance of the results on the resting pulse rate. We can but repeat that statistical examination is the only way to reveal whether such differences are significant. In a single person examined at different times and under different conditions it is possible that a variation of 10 beats per minute is within normal limits. But such variations occur in only a few of the subjects in our groups, and it is the uniformity of the changes of the remaining individuals in each group which really establishes the significance of the result by reducing the probable error of the mean change.—We are, etc.,

The Word "Rehabilitation"

SIR,—The word "rehabilitation" is subjected to much abuse in both medicine and law. I would attempt to define it. The rehabilitation of an injured or sick workman may be effected in three distinct ways: by prosthetic measures, by resettlement, and by reconditioning.

Prosthesis : where some extraneous, artificial aid is needed. This strictly applies to artificial limbs, etc., but it is no abuse of the term to include such things as spinal jackets, spring trusses, and pattened boots.

Resettlement : where ability to resume the regular trade or occupation is outside the bounds of reasonable probability. This applies to such medical states as heart disease, advanced phthisis, etc., and to any surgical condition where prosthesis is impossible or very inadequate—i.e., where there is a substantial measure of permanent incapacity.

Reconditioning : where resumption of suitable modified work is desirable or essential to secure a full or substantial measure of recovery. This applies to the majority of the Workmen's Compensation Act cases.

In my experience, the word "rehabilitation" has come to have such a laxity of definition that it now possesses no concise scientific or legal meaning. I would suggest that its use be discarded in industrial medicine and all medico-legal work, and that the three words (prosthesis, resettlement, and reconditioning) be substituted so as clearly to convey which form of rehabilitation the writer has in mind. Perhaps a discussion on this matter in your columns would give rise to an even better nomenclature.—I am, etc.,

Manchester. JOHN D. BYRD.

Staffing of Miniature Mass Radiography Units

SIR,—I feel indebted to Dr. J. V. Sparks for his observations (March 27, p. 398) and for endorsing some of my suggestions that have appeared previously in these columns. We seem to share agreement on most points.

One aspect of this subject, however, has not been fully considered (except for a short reference I made to it at a recent meeting of the Royal Society of Medicine), and that is the role of the "static" or stationary unit as compared with the use of the motor mobile portable unit in miniature mass radiography. When stationary units are employed the patient must travel to the examination centre and back again to his work. Distances must vary and the loss of time from work accordingly, while the necessary transport for these workers will further tax the public services, already overtaxed. Assuming that one *x*-ray unit carries out 5,000 examinations per week and that only 30 of these units are operating throughout the country: allowing 30 passengers to a bus for a double journey to and from the centre, then some 10,000 bus loads per week will be proceeding throughout the country to cope with this new form of medical examination. As time goes on this figure must increase, and sooner or later business firms may complain of the loss of man-hours, while the question of feeding these workers while away from work will arise; and who pays for the transport? During the war numerous new factories have sprung into being, situated over the countryside and often long distances from towns, which may mean that travelling to and from the centre will occupy the best part of a day or more.

It seems to me, as I have previously indicated in these columns (Aug. 29, 1940), that the solution will eventually prove to be the motor mobile portable miniature mass radiographic unit. The first of these units, which I had constructed through the British Red Cross in 1939, was eventually presented to the R.A.F. Medical Service, where it has done much useful work. This unit, however, was essentially an experimental one, and subsequent models are greatly advanced. The features and performance of the mobile portable unit as compared with the static unit are practically identical, except that the mobile units possess a distinct advantage in a shorter exposure time for making the actual *x*-ray exposure. This has been achieved by increasing the electrical cycles to the neighbourhood of 100, instead of retaining the customary 50 to 60 cycles which predominate on the average electrical mains. The power for the mobile unit is derived from a rotary coupled by a special fitting to the car engine, and the power led by a long cable, fed from a rotating drum (on the side of the car) to the *x*-ray unit, which has been assembled in the factory, office, or other place on the premises where the examinations are to be carried out. The *x*-ray tubes, the camera, lens, and transformer are the same on the mobile portable unit as on the static unit. The remainder of the machine, however, is constructed lightly and in sections, which permits rapid assembly or dismantling in a few minutes. The inside of the van is constructed as a dark-room to carry out development of full-size *x*-ray films or for miniature radiography work. Enough space is left in the centre of the van to load the portable unit and so transport it to the required destination. On arrival it is unloaded and quickly assembled in the factory or on the site of operation. The examinations are not carried out in the motor van itself, and thus the patients are not exposed to the rigors of the British winter, which they might be if they had to pass from the building to the van and back again.

In brief, we bring "the mountain to Mohammed," and what a saving of time, transport, man-hours, and money a fleet of these cars would effect if they were sent out into the country to visit the factories, warehouses, and stores instead of the masses of workers that will travel about the country in 10,000 bus loads a week under the present scheme for static machines! Further, the use of motor mobile portable units must be apparent for the examination of troops in outlying districts, civil population in rural areas, or in such places as the prairie provinces of Canada. While the present policy of the Ministry favours static machines, I feel convinced that before this new branch of work is much older this policy will be revised and the mobile units come into their own. Also for the static units that do have their place in the scheme, a much vaster organization will become necessary with specially designed centres, with large dressing halls on either side of the examination room capable of coping with hundreds of people at one time and permitting a properly organized one-way traffic system, so keeping the units properly fed with patients. These departments will also embrace all the customary conveniences Dr. Sparks has referred to (March 27, p. 398), reporting rooms, storage, and an extensive filing system.

I would welcome any criticism, destructive or constructive, concerning the use of the motor mobile portable miniature mass radiographic unit.—I am, etc.,

London, W 1. NORMAN P. HENDERSON.

Appointments System at Fracture Clinic

SIR,—Mr F. S. A. Doran's article on out-patient organization (April 3, p. 420) describing the appointments system employed in the fracture clinic at Manchester Royal Infirmary is most interesting; I know from personal experience at that clinic that the system works well in practice. I would criticize the following two points in it, however.

Although return cases are not kept waiting, new patients are kept waiting until 2 p.m. suffering from apprehension if not also from some degree of pain for the whole of the morning. The appointments record demands the co-operation of a clerk and the surgeon, and "the time, day, and date must all be written on the patient's appointment card." In spite of all these precautions one in every five patients fails to keep his appointment.

At the fracture clinic at the Glasgow Royal Infirmary over 7,000 new cases are now being treated each year. Most of the cases are fractures, dislocations, or sprains, and therefore the patients have to make subsequent attendances. The medical staff consists of a surgeon, first assistant, second assistant, and two house-surgeons, and the clerical staff of one secretary and one shorthand-typist: all are full time. On his first visit the patient is given his attendance card, which states that on subsequent visits he must attend at 10 a.m. (A–H); 11 a.m. (I–Mc); noon (M–Z). The letters refer to the initial of the patient's surname, and the two inappropriate times are deleted. For this area of Scotland such a division spaces patients equally throughout the morning, and each patient is automatically given an appointment as regards the hour for all subsequent attendances.

The case notes are filed in three cabinets, and so if the clerk has to go into cabinet 1 for an 11 a.m. patient she can reprimand him for having come late. Afternoon appointments are only made for special cases. As regards the day of subsequent attendance, the doctor seeing the case decides this and tells the patient: at the same time he marks it at the end of his notes as so many days hence—e.g., 7 indicates that the patient should report back in a week. At regular intervals the files are examined and all non-return cases weeded out; if necessary the department's almoner investigates the reason for the patient's absence. Most new cases arrive at 9 a.m. and so 9 to 10 a.m. is reserved for dealing with them, but two of the doctors are always detailed to carry out the treatment of a new case as soon as an *x*-ray is available. I feel that it is wrong to have to consider an appointments system for new cases as Mr. Doran suggests. So far as possible patients with different classes of fractures are asked to return on different days of the week. These groups of fractures are arranged so as to equalize the number of return cases each day.

By using this automatic system of appointments based on averages most patients are seen within half an hour, and no patient is kept waiting for more than an hour, and the cost in time and energy of the medical and clerical staff is reduced to a minimum. In practice the number of patients attending at the wrong time is certainly not more than the 20% which is the figure given for the Manchester Royal Infirmary fracture clinic. The greatest difficulty is in getting patients from a distance to complete their attendances. About 3,000 of our cases come from Lanarkshire, and the only way in which we have got over this difficulty has been to transport a mobile team and the patients' records to a local clinic which we have opened in Motherwell, the central town in the area of Lanarkshire served by this hospital.—I am, etc.,

Glasgow Royal Infirmary. JAMES PATRICK

SIR,—Mr. Doran, in his article on the out-patient organization of the fracture clinic at the Manchester Infirmary, shows how an appointments scheme can be applied in the case of old patients attending a department dealing with about 2,500 patients a year.

At Guy's Hospital for the last fifteen months an appointments system for all patients, both new and old, has been in force in the out-patient department, which dealt with 75,000 cases in 1942. So far as new cases are concerned, the patient or his doctor may book an appointment by personal visit, by letter, or by telephone to the sister-in-charge of the out-patient department. Old patients at each visit book appointments for their next attendance. Appointments are made in hourly blocks, one batch of patients attending, say, between 9.30 and 10.30 a.m. and the next between 10.30 and 11.30 a.m., so that no patient should have to wait longer than an hour before seeing the doctor, and some may see him within a quarter of an hour of their arrival. The number of patients booked for each hour varies in different clinics and was determined by analysis of the previous habits of each clinic.

Mr. Doran seems to express some doubt as to whether teaching can be undertaken in clinics which have adopted an appointments scheme. But his scheme aims at seeing patients at the rate of 15 to 20 every half-hour; obviously this does not permit teaching. In our scheme the number of appointments made per hour for the members of the teaching staff, both senior and junior, is considerably less than those made, for instance, for the house officers. We have not found that teaching renders the appointments scheme impracticable, and on the whole it has actually been of benefit to the teachers.

Our experience has been that the appointments scheme presents more advantages than objections. It certainly succeeds in its main object of curtailing the period of waiting. It represents an attempt to increase the efficiency of the out-patient department. It gives the patient the desirable impression that he is an individual and not one of a crowd. It relieves congestion in the out-patient hall. It permits the nurse to prepare more efficiently for the management of the session. It allows alterations in the out-patient time-table, unfortunately occasionally necessary in these difficult days, to be made at very short notice. It makes it possible to restrict the number of cases seen at any one session, and therefore assists a member of the visiting staff to plan his day with reasonable accuracy.—I am, etc.,

Guy's Hospital, S.E.1 P. M. F. Bishop, Deputy Superintendent.

Trichlorethylene Anaesthesia

Sir,—I read the two papers on trichlorethylene anaesthesia (March 27, p. 380) with great interest, as I have been using this agent for some time, both for routine work and for maxillo-facial and neurosurgical cases. While my own observations agree to a large extent with those made by Drs. Gordon, Shackleton, Howarth, and Duff, I do not think their conclusions do justice to a valuable and relatively harmless anaesthetic agent.

Of the cases quoted by Drs. Gordon and Shackleton 76% were intubated, and it seems at least possible that many of the cardiac irregularities reported may have been caused (or aggravated) by the presence of the tube in the trachea while the patient was in a light stage of anaesthesia. It has been conclusively demonstrated by Reid and Brace (*Surg. Gynec. Obstet.*, 1940, **70**, 157) that the insertion or removal of an endotracheal tube under light anaesthesia frequently gives rise to auricular and ventricular extrasystoles, with delayed conduction time and slowing of the heart, probably due to reflexes from the upper respiratory tract to the heart.

As anaesthetist to an E.M.S. maxillo-facial clinic, I consider that the original technique of Magill has yet to be surpassed. This consists of nitrous oxide and oxygen, with or without carbon dioxide absorption, and supplemented by a minimal amount of warmed ether vapour administered by the drip-feed method. For those cases in which diathermy is used, or when for other reasons ether is contraindicated, trichlorethylene is used to supplement the nitrous oxide–oxygen with excellent results. Although many patients can be intubated without difficulty, better results are obtained in the robust "Service" type of patient by preliminary induction with pentothal–nitrous oxide–oxygen–ether until the patient is well established in the third or surgical stage of anaesthesia. As in the case of chloroform, this procedure eliminates the "dangerous" period of light anaesthesia when cardiac irregularities are liable to occur. Subsequent anaesthesia may be maintained by trichlorethylene, so that by the end of the average plastic operation the ether will have been eliminated from the patient's system.

It is true that trichlorethylene does occasionally give rise to various forms of cardiac irregularity, but with suitable precautions and technique this complication should not be unduly prominent. During the past nine months I have administered trichlorethylene to about eighty patients undergoing operation for brain tumour, trigeminal neuralgia, and other neurosurgical affections. Although nearly all these patients were induced and intubated without ether, cardiac irregularities have been observed in only six cases, three of which were classified as bad risks before operation. All cases undergoing intracranial operations were anaesthetized by the open T-piece technique which I described some years ago (*Lancet*, 1937, **1**, 561). Anaesthesia is maintained in the first plane of the third stage for long periods up to six hours, and the results have been so satisfactory that trichlorethylene is now used as a routine for neurosurgical operations. After induction and intubation the nitrous oxide is set at 2 to 4 litres and the oxygen at 2 litres a minute, the gases being passed over the surface of the trichlorethylene; when the bone-flap has been turned down, the nitrous oxide is usually discontinued and the oxygen flow increased to 4 litres a minute. With the T-piece technique a certain proportion of air is admitted to the circuit, which may account for the fact that the respiratory rate rarely rises above 25 to 30 a minute. About 1½ to 2 ounces of trichlorethylene is used during an operation lasting four hours, and, not infrequently, the patient is able to answer questions when the endotracheal tube is removed at the end of the operation.

While no one would suggest that trichlorethylene is a universal anaesthetic agent, nevertheless it is a most useful one for suitable cases, especially in the presence of the diathermy or thermocautery. In my opinion it should not be administered when gross toxaemia or cardiac irregularities are known to be present, or to very young children; nor should it be used if there is a marked and progressive rise in the rate of respiration during operation.

By the way, can anybody tell me why the respiratory rate increases during trichlorethylene anaesthesia?—I am, etc.,

Newcastle-upon-Tyne Philip Ayre.

Peptic Ulcer a Deficiency Disease?

Sir,—As a contribution to Dr. J. J. O'Mullane's view (March 6, p. 302) on the subject of peptic ulcer as a deficiency disease may I report on two cases of my own. They concern two female patients, aged 19 and 25 respectively, under my care early in 1937 in Vienna, who suffered from gastric ulcer, confirmed by *x*-ray examination, and whose histories were very alike. Neither of them responded to the usual treatment, for in spite of rest in bed, strict diet, etc., for many months they kept on having pain after food, and occult blood in faeces. In the course of their illness they developed classical signs of scurvy. Put on vitamin C, in addition to ample lemon and orange juice, not only did the scurvy clear up completely after four weeks but there was a remarkable improvement of the gastric condition as well; and kept on the vitamin for another six weeks they made a perfect recovery from the ulcer. Radiographs taken a few months later showed no pathological changes.

Whether the scurvy was due to the diet—the liberal Meulengracht diet not yet being adopted, and the ulcer diet at that time being not only insufficient in calories but deficient in, almost devoid of, vitamins—or whether the ulcer itself was the result of vitamin deficiency (the girls came from working-class families, for years unemployed and their food conditions poor) I leave undecided. But the striking effect of the vitamin therapy in those two cases, the definite, although less dramatic, improvement in other cases of gastric ulcers which I had to deal with subsequently, and, further, the clinical experience that both acute and chronic ulcers are more frequently met with during spring, when vitamin-containing foods are getting scarce, strongly suggest a connexion between peptic ulcer and deficiency of vitamin, probably vitamin C.

If we regard the peptic ulcer as a disproportion between acid production and resistance of the stomach mucosa, it might be supposed that lack of vitamin presents one of the factors which leads to devitalization and eventually to digestion of the mucosa. Vitamin deficiency may also be the explanation of the well-known fact that although the single defect may heal up, or at least be reduced to a state of latency, yet the tendency to recurrence—the "ulcus diathesis," as H. Strauss puts it—remains.—I am, etc.,

Manchester B. Kohn.

Houses to Live In

Sir,—I am wondering if it may not be in proper place for me to comment on the article in your *Journal* entitled "Houses to Live In" (Jan. 30, p. 136). I have thought a great deal about the inadequacy of houses constructed during my lifetime. Over large portions of the United States they are hideous and, in many respects, unsuitable for the usual domestic arrangements. However, we have succeeded, in the last decade at least, and are succeeding in a larger degree to-day, in building successfully designed dwellings.

There is almost nothing in your comment on the memorandum of the Royal College of Physicians which would indicate that a suitable dwelling had been recommended, or indeed could be constructed from the outline given in your columns. Why, for instance, should communication between the bathroom and bedroom be forbidden? In this country the bathroom at the end of the hallway belongs to the Dark Ages. One bathroom should be placed between every two bedrooms. If a maid's room is constructed it should have, as it does in the United States, a separate private bath; if the maid lives out, there should be at least a toilet and wash bowl off the kitchen. The cost of bathroom installations in this country is so low that it need not be considered an obstacle in correct planning.

Nothing in your editorial indicates adequate planning as to convenient arrangements for housekeeping even should it envisage a standard of living compatible with a very low wage

Nothing is said about the durability of construction materials, particularly finishing materials, and their relation to sanitary arrangements and attractiveness. Why should there be a discussion about a dustbin? In this country I don't think we know what it is. Is central heating never coming to the English dwelling? The comments about housing for "the dirty and the anti-social" sound primitive. Why not either exclude them from communities where decent standards prevail or let education and the attitude of their neighbours contribute to making them more desirable tenants?

The College's three-story house brings up an unsavoury and unattractive picture. It seems too bad that the members of the College could not visit the United States and see some of the community dwellings which have been constructed over the past several decades by various philanthropic foundations and more recently by the Government itself. They provide separate dwellings in attractive style and with well-considered household arrangements, the buildings being "hooked up" so as to give some of the constructional advantage of a multiple dwelling.

The contrast between the sanitary arrangements now available in Europe, or even considered possible in Europe, and the everyday accommodations in this country needs to be remedied. I remember how astonished a British lady of distinction was several years ago to find that she could take a bath in the bathroom adjacent to her bedroom where she was a guest without having to make way for the next bather. To her it was unheard of that in a multiple-room dwelling there should be a bathroom with every bedroom.—I am, etc.,

New York. H. SIDNEY NEWCOMER, M.D.

What of the Patient?

SIR,—In the letters that you have so far published about the future of medicine in this country I have seen very little that deals with the part the patient will have to play. A comprehensive health scheme is much more than a matter of professional organization and free choice of doctor. The sick and the potentially sick will come into quite a different relationship with the State once any such service is initiated. It is most unlikely that the State will waste money on the treatment of conditions caused by gross neglect or deliberate ignorance. Clearly the patient will have to "toe the line" quite as much as will the medical profession.

While the free choice of doctor might conceivably be kept, the choice will have to be confined to a registered practitioner and the unorthodox will have to go out of business. The scheme will be made into a farce if the organization of the medical profession merely results in a gross increase in the number of "quacks." Self-medication and the scandals of the patent medicine business will have to be dealt with, for if anyone needs medicine he should get it through the doctor and the Government pharmacist. Treatment of socially dangerous diseases will have to be made compulsory. Many more positive steps will have to be taken to prevent ill-health. It should be a serious offence for parents to neglect to give a child pure milk in adequate amounts or to neglect to give vitamin supplements or such other substances as are deemed necessary. The disgustingly filthy houses that one sees, and not all in the poorer parts of towns and cities, must be cleaned up and kept clean. The laws relating to the supply of foods and drink will have to be tightened up. All these, and many other points that will readily occur to medical men, have their place in any real plan for the future health of this country.

Further, as measures of more immediate import, the whole field of animal research and of prevention of disease by vaccines and sera will have to be reviewed. Inoculation against diphtheria and such other types of preventive treatment as wide experience shows to be desirable will have to be made compulsory. This will raise opposition, but I think that this should be met with now. Illness that is preventable must be prevented, otherwise the idea of raising the standard of health of the country becomes a mockery.

There are many doctors who fear that the only result of the agitation that is now going on will be the coercion of the medical profession and its organization into a State-controlled body that will then be expected to do wonders in improving the health of the people. What is the public going to do as its share of this great work? There will be great changes in the habits of the people when these plans are brought to fruition, and it is time that this was brought to the attention of the general public.—I am, etc.,

Bristol. J. N. P. DAVIES, M.B., Ch.B.

Artificial Respiration

SIR,—The knowledge of physics required by the medical curriculum is admittedly elementary, but it is distressing that so many of our profession have forgotten even the rudiments of the subject. In artificial or any other respiration the force with which we are dealing is atmospheric pressure. This force, a result of gravity, differs from its parent in that it is exerted in all directions.

In respiration the problem is not to get air into the lungs,—atmospheric pressure does that—but to get it out. Eve's method uses the effect of gravity, in moving the liver and spleen (total 36 lb.) down an inclined plane, to push the air out of the lungs. Schafer calls for compression of the abdomen to force the diaphragm into the thorax. The actual measure of efficiency is the volume of tidal air produced in a moribund body. Eve's method demands at least a plank and a fulcrum; it cannot be used at low tide on the Solway: Schafer's can.—I am, etc.,

E. J. THOMSON.

Scientific Freedom and Social Medicine

SIR,—Mr. Somerville Hastings (March 27, p. 392) has misunderstood my paper. He has assumed that it is an attack upon State medicine, and, in defence, he has rallied a rather unrelated mixture of statements, opinions, and criticisms. I attempted to demonstrate, by analysis, that the medical superintendent system is unsatisfactory as compared with that of management of a hospital by a properly constituted medical committee. The prospect of State medicine raises this issue to a position of paramount importance, and it is essential that medical men be made aware of the bad points of an autocratic system and of the danger of instituting it.

Mr. Somerville Hastings has therefore been belabouring the wind, and I must apologize to him for having caused such a waste of his energy. In so far as he touches upon the question of the control of medical affairs within the hospital, he makes no defence of the medical superintendent system, and brings forward no argument against government by committee. He pleads for specific examples of bad superintendents, but I am sure that he, as a Socialist, would not base his rejection of the principle of absolute monarchy entirely upon the examples of Nero, James II, and their like. He cites the great improvement of the L.C.C. hospitals, which I heartily endorse, but again I cannot follow his train of argument. I seem to remember British reactionaries praising the punctuality of the Italian railways under Fascism. The logic is parallel.

In plain fact, the medical superintendent in council and municipal hospitals has absolute power as regards medical affairs, as well as administratively. Mr. Hastings's statement that "the work of junior medical officers in municipal hospitals is under a degree of supervision and even control by senior officers" is a tribute to his belief in human benevolence, but is misleading. In fact, every medical officer, junior and senior, in every council and municipal hospital is under the complete autocratic control of one man—the medical superintendent. The superintendent can impose treatment upon, or withhold treatment from, the patients who are under the direct care of the other medical men in his hospital. He can remove patients from any wards, and, if he has surgical aspirations, submit them to any form of specialist surgical procedure at his own hands, remaining above all criticism respecting the results. Should a junior desire to write an M.D. thesis, access to cases may be made conditional upon his consent to bracket the superintendent's name with his own in the event of publication. These things can all be done, and the nature of the system conceals them from the public and from the profession. But the sterilizing effect in an autocracy is produced less by the rare major misdeeds than by the minor misdemeanours, which are more frequent in proportion to their lack of sensationalism. So long as this state of things is confined to one small section of active medicine it matters little, but if the autocratic system were made universal under State medicine the result would be sterilizing to initiative and to research.

Mr. Hastings thinks that there is freedom of scientific publication in a municipal service. I would like to refer him to the Standing Order 303 (Sections *a, b,* and *c*) of the London County Council. He will find that scientific papers have to be submitted to a higher authority, which will determine whether any question of policy is involved. Now, the central authority can define and impose the limits of policy, and the paper in question may well be one dealing with the details of medical or surgical treatment, blood transfusion, immunization, and so on *ad infinitum,* and a reversal of policy, even if it were beneficial to the patient, might throw discredit upon the lay or medical initiators of the policy. My view of politics is, perhaps, less roseate than that of Mr. Hastings, but I suspect that many men in authority rather dislike being proved wrong by their juniors, and this is especially true of politicians and of scientifically rusty administrators.

Mr. Hastings does believe that "at every hospital there should be a committee of the medical staff through which individual and collective viewpoints can be expressed and transmitted to the governing authority.". He does not state whether he thinks that these committees should exist, like the present Reichstag, as emblems and gestures only or whether they are to be regarded as responsible bodies empowered to transmit the opinions of the staff as a whole to the lay power. If the progressive parties in the State do not quickly formulate their policy upon this matter, they will forfeit the support of a large mass of medical opinion which honestly desires to see the best possible medical treatment administered as widely as possible.

In conclusion, I would like to ask Mr. Hastings the following questions:

1. Does he believe in democracy in science—that is, in real unrestricted freedom of speech and criticism?
2. Is he in favour of retaining the autocratic power as regards medical affairs in the hands of the medical superintendent?
3. If medical committees are instituted, does he think that these should have local freedom to elect their own chairman and officers, and to express their opinions to their lay bodies without other intermediary?

If his official position makes it impossible for him to reply, I suggest that he ascertain the answers from his lay authority with their permission to make them public. Failure to do this will carry its own implication. Medical men throughout the country should ask similar questions of the municipal bodies and councils with which they are or may be concerned.—I am, etc.,

London, W.1. GEOFFREY BOURNE.

SIR,—Having, with but four years' break, been in the service of the Council or its predecessors since 1908 I write to endorse what Mr. Somerville Hastings (March 27, p. 392) says of the improvement in the general hospitals of the L.C.C. since April 1, 1930. That they can learn from the voluntary hospitals I agree, but I am also confident that voluntary hospitals could learn from them.

The suggestion that some hospital is "run exclusively for the benefit of the doctors or its staff" has previously only been made in jest or in pique, usually by a tired surgeon in reference to the nurses when all the theatre staff have been changed on one day, but this is the first time I have ever heard it suggested that the administration of any hospital should be under its medical staff. Either there is a hospital board to which two or more members of the medical staff may be appointed or, as at Guy's, the staff form a medical committee which acts as the advisory body to the Governors in all expert matters affecting the care of the patients, but has no say in the general administration, including finance, works, supplies, intercommunication, and the nursing, radiographic, and massage departments and schools. There may be different views as to how a hospital should be run—and I believe there is room for two systems competing in friendly harmony, and each doing the work suited to it—but everyone conscientiously thinks that what he does is in the interest of the sick. Even the traditional tyrannical medical superintendents believe this; but shall we gain anything by producing concrete examples of their failings? Had we not better thresh the matter out on principle and so avoid the bickerings of personalities, while setting up an organization that will prevent such a man making the life of everyone in the place miserable when he gets into power? We cannot prevent one such being appointed from time to time. We do not know enough about the psychology of the power complex. Its possessor may not know he has it, or it may not enter into him until he attains to the position where he can use it. Alternatively, he may so mask his true nature from those appointed to appoint him that they think they have made an excellent selection, though all who have previously worked with him shiver at the announcement. No doubt concrete examples will be forthcoming if they must, but Mr. Somerville Hastings will be the last man in the medical profession to hear of them because of the political post that he holds.

There is a principle well recognized in the fighting Services, and we need to make sure of it in the civilian medical services as they develop. It is based upon the rule of English justice that anyone is entitled to be judged by his peers. A sailor is tried by a sailor, a lawyer by a lawyer, and a doctor by a doctor in all matters of professional behaviour. Let us apply that principle to Mr. Somerville Hastings. He is the chairman of the Hospital and Medical Services Committee of the L.C.C., but he holds that post as a politician and not as a doctor, and the last person to whom we want our professional differences to go is a politician. If concrete cases are needed they will be asked for by those appointed to make the "further immediate investigation" (Beveridge report, para. 437), the organization for which is at present being set up, but if the whole matter can be settled on first principles so much the better.—I am, etc.,

Guy's Hospital, S.E.1. T. B. LAYTON.

SIR,—There are few who will disagree with Dr. Geoffrey Bourne's resolutions regarding a State hospital service (Feb. 20, p. 227), but some of his arguments reveal a point of view which, I think, cannot go unchallenged.

He says: "Doctors have, or should have, as their only professional objects the provision of the best possible preventive measures against disease, the best possible administration of treatment, and the most rapid improvements possible in the technique of treatment. They are concerned greatly in the facilities given them for this purpose and demand that they shall be the best procurable, but *care little by what machinery these facilities are paid for.*" (The italics are mine.) If this last-quoted sentence is true it indicates a peculiar gap in the mental horizon of doctors. The machinery by which payment is made profoundly affects the relationship between doctor and patient, and has a bearing on the standard and type of treatment received, or may even determine whether a patient is treated or not. Even if the statement were true about most doctors (which is very doubtful), it is certain that the leaders of the profession care a great deal by what machinery the facilities they supply to the wealthy patient are paid for.

The attitude towards patients is different in voluntary and municipal hospitals, precisely because treatment is paid for in different ways. A voluntary hospital is provided *for* the patient, but not necessarily *by* him. Expressed somewhat crudely the attitude taken by the hospital towards him is, "Take it or leave it." The hospital is run, not as Dr. Bourne says by a democracy, but by an oligarchy, whether intentionally or not and however "democratic" the leaders may appear to be towards their juniors. This is partly due to the high professional (and often social) position of these leaders. It results in patients being regarded as "good cases," "opportunities for practice," "means of building a reputation," or "material for research"—a statement which casts no slur on the efficiency or humaneness of the treatment they receive individually. It means that selection of cases can be exercised for teaching or research purposes or for reasons of personal interest.

A municipal hospital is owned by the patients. They pay for its construction, upkeep, staffing, and management, so they cannot be regarded in quite the same way. They can demand treatment there, and the staff, as a whole, cannot exercise selection. This system has involved the establishment of medical superintendents, who are placed in a very responsible position between the patients and the lay committees, to whom complaints are reported. This is why a medical superintendent feels that he must have some control over any scientific work done in his hospital; the "material" for such work is not only paying for it, but is the owner of the means by which it is done. Similarly, the remark of a lay member, quoted by Dr. Bourne, to the effect that "I will not have *my* people taught upon for the benefit of medical students," simply indicates an acute consciousness of the position of the patient in the system.

Looking at the matter historically I cannot see any way by which the magnificent series of publicly owned hospitals, exemplified by those of London and Middlesex, could have been brought to their present standard of efficiency except by perpetuating for a time the already existing machinery. It could not have been effected by transferring the "voluntary" type of oligarchy to the municipal hospital, because the method of working would not have fitted in with the rate-paying system.

But if the modern medical superintendent is the natural successor to the one who "ran" the infirmary, he is usually a very different type of person. Many superintendents have been doing first-rate clinical work, besides performing their arduous administrative duties and in addition to their efforts in building up efficient hospitals and staffs. I have no experience of L.C.C. hospitals, but, having attended staff meetings at a Middlesex county hospital every week for the last 3 years, I can assure Dr. Bourne that he is wrong in saying that these meetings were "a great concession," started in order to "divert criticism," that they are "devoid of power" and have "no power of initiation." Proposals from members of the staff at these meetings are, where possible, carried out or attempted, and on occasions the medical superintendent is overruled, either by force of numbers or by a single authoritative voice.

I should like further to draw Dr. Bourne's attention to the fact that the Middlesex county hospitals have had for some years a flourishing medical society. This body has recently formed a research committee, which is at the moment making plans for the co-ordination of clinical research within the Middlesex county hospitals. The initiative for this enterprise has come from the medical officers forming the society and has in no sense been "dictated" from above; it has, however, received the warm support and encouragement of the medical superintendents of the several hospitals. It is a free movement within a socialized system and is to my mind indicative of the sort of team activity which is going to be a feature of the municipal hospital system. But I agree with Dr. Bourne that the "dictator" must disappear and the hospital system become democratic. In order to make it so, however, there must be removed from the present hotch-potch not only the dictator element of the municipal hospitals but also the oligarchy of the "voluntaries."—I am, etc.,

South Mimms V. C. ROBINSON.

Anatomical Nomenclature

SIR,—In a well-known journal the reviewer of a book on surgical anatomy deplores the use in the book of the Birmingham anatomical nomenclature in preference to the old terminology. His justification seems to be that the latter is still the more generally known, and from that fact he argues that it is the more valuable in practice and therefore ought to survive. This attitude of mind to new developments has been manifest throughout the history of man, and has been one of the principal deterrents of the advance of scientific knowledge. Nearly all discoverers of new principles have had to run the gauntlet of criticism by those in whose minds was rooted the conviction that what they had been taught was correct, and who would not bestir themselves sufficiently to give serious consideration to the new ideas. In the same way the reception of the different changes in anatomical nomenclature has been hostile and even derisory in many quarters. These critics all have one thing in common, however, and that is that they have not troubled to study the newer terminologies. Had they done so, they would surely have recognized that each change represented an advance towards the rationalization and simplification of a difficult subject. The object of those concerned in making the changes has been progress, and the same can hardly be said of the rigid-minded critics.

Thus, the Basle nomenclature was introduced as an international one, and surely none can deny that such a step as its adoption was in the right direction, both to breaking down the nationalism which has been so largely responsible for the present world chaos and to the avoidance of having to learn a completely new anatomical terminology for every language in which medical works were read. But its Latin terms were cumbersome and difficult for most British medical men, and the Birmingham revision represented a further advance for British anatomy because it resulted in a more rational terminology which, for English-speaking people, was easier to learn and to remember. It is true that the names of the early describers of the different structures are absent from the modern terminology, but this is no bad thing. Such proper names, applied to anatomical structures, give no indication of the position or nature of the structures concerned, while the modern names in most cases are descriptive and are thus, so far as possible, an aid to memory instead of an additional burden on it. Medical students should have some knowledge of the history of medicine, and the pioneers should therefore be known to them not just as names, which in themselves signify nothing, but as personalities.

At the present day the unsatisfactory position exists that many students are taught the modern anatomical terminology during their anatomical studies, and yet when they begin to study clinical subjects they find that they cannot understand the terms used by their teachers and vice versa. Since the teachers are not prepared to change their terminology the students must, in their own interests, set about learning a completely new nomenclature just at the time when their memories are being taxed with the many and varied details of the clinical subjects. It seems likely that this handicap will be imposed on students until the clinical teaching is done by those who have been taught the new terminology and who realize its advantages over the old.

The same type of difficulty is encountered by the student in the use of weights and measures. In the pre-clinical years he is trained to use the rational and admirably simple metric system, and great is his confusion when, on reaching the clinical subjects, he is plunged into the intricacies of the curious and haphazard British system (if it can be called a system) of weights and measures. In this respect medical science is slow in following the lead of the other sciences in using the best form of expression, and it is for the teachers of medical subjects to cut short the time lag in the adoption of a rational system both of measure and of anatomical terminology.—I am, etc.,

University of St. Andrews HERBERT HAXTON.

Venereal Diseases

SIR,—In your issue of March 13 your correspondent Dr. E. A. Chartres raises matters which are of vital importance to the health of the nation. At the V.D. Conference on Feb. 26 the fundamental issue of prevention by scientific means was carefully avoided by nearly all the speakers, while the practical application of prevention, such as that now being carried out by the Bournemouth Town Council, was not touched upon at all. The Archbishop left the matter in a position in which it cannot be allowed to remain, and the official policy of the Ministry must be challenged on the scientific aspect of the problem.

From the scientific point of view the position is amazing. The provision of additional sex education generally, and about V.D. in particular, is being urged, while all the time every opportunity is taken to prevent the scientific facts about prevention becoming known. Prevention is being prevented. The scientific research upon which V.D. prevention is based is as brilliant and as conclusive as any on record, and experience in the last war abundantly proved its reliability and added to our knowledge. Fanatical obstruction is such that it is demanded that this vitally important knowledge should be withheld from men and women. Although the Archbishop says, "an immense amount of sheer ignorance and error is to be dispelled," he deplores the spread of scientific truth about preventing V.D.

Fanatical opposition knows no limit. The Services are charged with "deliberate condonation of fornication" by giving instruction in the use of prophylactics. In other words, it is suggested that the responsible heads of the Services, knowing full well that venereal disease can be easily prevented, should deliberately fail to use that knowledge, and thereby allow thousands of our young people to fall victims of the disease. By forbidding any mention or use of prophylactics these opponents would condemn "sinners" *unnecessarily* to grave physical injury, with probable spread to numerous innocent persons. Fortunately, our Services are run on more enlightened principles. These same opponents of prevention urge the provision of more and more clinics where the infected "sinners" can be cured at great expense to the community. In fact, their case boils down to a demand that "sinners" must run the risk of catching the disease, but, once infected, they must be given the advantage of scientific discovery in order to be cured. The use of other scientific discoveries which can and will prevent these diseases would not be allowed if such people had their way.

Properly organized and administered, a crusade against V.D. by scientific prevention could and would eliminate these foul scourges from our midst. Suitable posters and cards of simple directions for men and women have been prepared by the National Society for the Prevention of Venereal Disease, 47, Nottingham Place, W.1, and are now being circulated to all local authorities. In Bournemouth hundreds of these posters have been displayed, and thousands of cards with clear and concise instructions have been distributed by the Health Department. This is sound practical prevention.—I am, etc.,

R. A. LYSTER,
Chairman, N.S.P.V.D.

Bournemouth.

Irritant Spectacle Frames

SIR,—I believe I have made the acquaintance of a new form of allergy which may become fairly widespread. Two of my patients, who are, luckily, neighbours, have discussed with me their experience after obtaining new spectacle frames of wartime "tortoiseshell." Both have obtained their spectacles from the same optician within recent weeks. Both have noted intractable itching behind the ears, accompanied by serous discharge of considerable volume. Mrs. A. has also found a slight reaction on the bridge of the nose, while Mrs. B. has to-day a linear erythema across the temple, exactly where the sidepiece of the spectacles lies.

I write in the hope that this observation may help others. —I am, etc.,

H. THISTLETHWAITE.

Preserving Medical Freedom

SIR,—In view of the present interest in the question of hospital organization we thought it might interest your readers to know of the following resolution which was passed at the last meeting of the Medical Council of St. Bartholomew's Hospital. This resolution has been considered by the treasurer and governors of the hospital, who have expressed themselves in full agreement therewith.

"The Medical Council regards it as essential that freedom of expression in medical matters, freedom of speech, and freedom of medical practice in hospitals must be preserved in any post-war reconstruction and that a medical committee should be the advisory body to the governors of an institution on medical matters."

—We are, etc.,

REGINALD M. VICK,
Chairman.
F. C. W. CAPPS,
Hon. Secretary.

St Bartholomew's Hospital.

The Services

Prob. Temp. Surg. Lieut. J. A. Oddie, R.N.V.R., has been awarded the D.S.C. for bravery and skill in the hazardous operations by which the Allied Forces were landed in North Africa.

NAVAL MEDICAL COMPASSIONATE FUND

A meeting of the subscribers to the above Fund will be held on April 30, at 3 p.m., at the Medical Department of the Navy, 64, St. James's Street, S.W., to elect six directors of the Fund.

CASUALTIES IN THE MEDICAL SERVICES

Died from the Effects of Wounds.—Capt. G. M. Calder, R.A.M.C.

Previously reported Missing since the Fall of Singapore, now officially reported Prisoner of War.—Major G. O. Gauld, R.A.M.C.

Obituary

E. W. G. MASTERMAN, M.D., F.R.C.S.

The death took place in Jerusalem on March 29 of Mr. E. W. G. Masterman, who both began and ended his career as a medical missionary in Palestine and Syria, but in his middle years served as medical superintendent at a London hospital and took a prominent part in the central work of the British Medical Association.

Ernest William Gurney Masterman was born on Jan. 2, 1867, the son of James William Masterman of Rotherfield Hall, Sussex. He derived his third Christian name from his mother's family. He was the elder brother of the Right Hon. C. F. G. Masterman, one of the principal builders of the national health insurance system and the first chairman of the Insurance Commission, whose functions were taken over by the Ministry of Health. Ernest Masterman was educated at Clifton College and at Monkton Combe School. He turned to a medical career only as incidental to a missionary one. He began his professional training at Edinburgh University in 1884, and in Edinburgh his ambition to be a missionary was reinforced by contact with C. T. Studd, the well-known evangelist. But family circumstances brought about an interruption in his studies, and for a time he became a schoolmaster. In 1887, however, he entered St. Bartholomew's Hospital, where he was Brackenbury surgical scholar, qualifying in 1891. In the following year he found his way out East, on appointment as assistant medical officer of the Jerusalem Hospital of the Church Missions to Jews. From that time onwards, for fifty years, the Holy Land was the great interest of his life. He worked at Jerusalem, Safed, and Damascus, and again at Jerusalem, until the outbreak of the war in 1914 caused his return to England. In 1916 he was given the charge of St. Giles's Hospital, Camberwell, now one of the L.C.C. hospitals, and served there until his retirement in 1933 under the age limit. He then returned to Palestine, this time under the aegis of the Church Missionary Society, and had charge of hospitals in Es Salt, Transjordan, and in Gaza and Hebron. At the age of seventy-one he was made medical superintendent of the 60th General Hospital in Palestine, and in 1939 he was appointed medical adviser for the Near East to the Church Missionary Society.

During his years in London Masterman identified himself with the work of the B.M.A. He attended every Annual Representative Meeting from 1920 to 1934. In 1931 he came on to the Central Council, of which he was a member for four years. He had previously done good service on the Public Health and Hospitals Committees, and he also served on a number of special committees, including one set up in connexion with the Indian Medical Service. In the Camberwell Division and the Metropolitan Counties Branch he also did good work. He was chairman of the Division in 1928-9, and, after serving for three years as joint honorary secretary of the Branch, he became its president in 1934-5. In all that he did he was a "good B.M.A. man,' and his common-sense counsel and special experience were highly valued. The subject of maternity services specially interested him, and in this field he served as a member of more than one committee. He had taken the Fellowship of the Royal College of Surgeons in 1892, a few years later he took the Cambridge D.P.H., and in 1909 the M.D. of Durham.

His interest in Palestine, its past and present, never slackened. For many years he was secretary of the Palestine Exploration Fund. To return to Jerusalem and be able to spend his closing years there in useful and happy activity gave him much satisfaction. For some time, however, he had been in failing health, and his son, who was serving in the R.A.M.C. in West Africa, was able, with Mrs. Masterman and other members of the family, to be with him at the end.

The following well-known medical men have recently died abroad: Dr. ALLEN GREENWOOD, emeritus professor of ophthalmology, Tufts College Medical School, Boston, aged 76; and Dr. BERNHARD FISCHER-WASELS, professor of morbid anatomy at Frankfort-on-Maine, president of the German Pathological Society, editor of the *Frankfurter Zeitschrift für Pathologie*, and well known for his work on cancer research.

Universities and Colleges

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

Academic Postgraduate Diploma in Medical Radiology.—*Part I:* Patricia Franklyn, H. H. Hermann, D. D. A Jayamanne, Elspeth M. Ledlie, T. S. Leedham, M. G. Magan, B. Sandler, L. M. Shorvon.

The title of Reader in Medicine in the University has been conferred on Clifford Wilson, D.M., B.Ch., in respect of the post held by him at the London Hospital Medical College.

UNIVERSITY OF SHEFFIELD

The following candidates have been approved at the examinations indicated:

M.D—T R. Forsythe

Final M B, Ch B.—*Parts II and III:* L. Anderson, H. J Dooley, Marie France, G. L. Hermitte, P. B H. Howarth, R. A McFadden, D. S. Mall, R. B Peasegood, Ethel W W. Sharrard, H. J. Whiteley, J. Wilbush; Elena Zadik.

UNIVERSITY OF EDINBURGH

A graduation ceremony was held on April 5, when the following degrees and diplomas were conferred:

M.D—[1]G R. Lunn.

Ph.D—M. Y. Ansari, M B, B S

M.B., Ch.B.—H. Ali Ud-Din, [1]D. St. J. Bowie, I. A Brooks, G. Davidson, K G S. Davidson, R. A M Hamerton, T A Hope, H J. Mackay, A H MacKinnon, I. G. Maclean, J. M. G. Parker, R. W Pettigrew, T. M. Pole, J Rifkind, A E Smith, Margaret M. Timpany.

[1] *In absentia*

Prof. A. T. Jurasz conferred the first degree of M.D. in the Polish School of Medicine.

Medical Notes in Parliament

The Nation's Milk

During a debate in the House of Lords on April 1 on the remuneration of milk distributors, Lord **Perry** said the Ministry of Food now told the consumer that he must buy his milk from a particular tradesman and could only get the sort of milk which that tradesman sold. Tuberculin-tested milk continued to be produced; he himself owned a farm where it was produced. Clean milk, however, produced under ideal conditions in premises frequently inspected was tipped into a common pot along with dirty milk produced by less competent people. That was bad management and an outrage on the consumer. Lord **Bledisloe** said that if methods of production were economized and disease eliminated from the cattle, this country could produce the whole of the liquid milk consumed. In many countries besides Northern Ireland there had been an almost total elimination of bovine tuberculosis as the result of careful and drastic Government administration. Tuberculosis from bovine sources was practically unknown in New Zealand to-day. Lord **Geddes** said he feared the Ministry of Agriculture could not deny that clean tuberculin-tested milk was mixed with milk known to be infected with bovine tuberculosis and *Brucella abortus*, the cause of undulant fever, in the Government milk depots. It should be stated in the House that the children's milk was being deliberately contaminated by the Government.

Lord **Woolton** said he was not satisfied with the present position. The tuberculin-tested milk that could find a market was sold as such. The T.T. milk which could not find a market was mixed with other milk. When Lord Geddes had suggested that all other milk which went to children contained those germs he had been too pessimistic. Lord **Geddes** intervened to say there had been a statement by the B.M.A., and also, he thought, by the Royal College of Physicians, on this contaminated milk. It was proved by the medical profession that much of the milk produced in this country was infected with bovine tuberculosis and *Brucella abortus*. That milk was being mixed and, without pasteurization, was sold to the children. Lord Geddes added that, as Lord Woolton was to make a statement at an early date, he would not press the matter.

Nurses Bill: Position of Scotland

Mr. **Hannah** inquired on April 6 when it was proposed to introduce a Nurses Bill for Scotland. Mr. **Johnston** said the main purpose of such a Bill would be to establish a roll of assistant nurses, a proposal which the Alness Committee reported against in 1938. In view of the altered conditions since that date he was having discussions with the Scottish nursing and other organizations concerned. He hoped to make a statement shortly.

Medical News

The Ministry of Food announces that from April 18 capsules and tablets made from specially concentrated fish-liver oils will be available for expectant mothers under the vitamin scheme. Each capsule (or tablet) contains 4,000 i.u. of vitamin A and 800 i.u of vitamin D. They will not be available to children receiving fruit juice and cod-liver oil under the vitamin scheme. The capsules and tablets are to supplement the vitamin A and D intake of expectant mothers. The Ministry has recognized that many mothers could not take the cod-liver oil provided for them and their young children. They will be distributed through the existing chain of distributing centres (welfare centres, clinics, and food offices). Expectant mothers will use the cod-liver-oil coupon sheets obtainable from many food offices in order to get the capsules or tablets. They may take them or cod-liver oil, as they wish. Future supplies of cod-liver oil under the scheme will contain double the present quantity of vitamin D The new oil will therefore have a minimum vitamin D potency of 200 international units per gramme.

The House of the British Medical Association will be closed from Thursday, April 22, 6 p.m., to Tuesday, April 27, 9 a.m

The inaugural lecture under the general title of "The Health of the Child" will be given on Wednesday, May 5, at 5 p.m. in King's Hall, King's College, Newcastle, by Prof. J. C. Spence, M.D., F.R.C.P., first holder of the chair. Through the generosity of the Nuffield Provincial Hospital Trustees, Durham is the first university in the Kingdom to establish such a chair. Tickets of admission may be obtained from the Registrar of King's College, Newcastle-upon-Tyne, 2.

At a meeting of the Medico-Legal Society to be held at 26, Portland Place, W., on Wednesday, April 21, at 5.30 p.m., a joint paper will be presented by Drs. J. C. M. Matheson and J. D. N. Hill on electro-encephalography in medico-legal problems.

At a meeting of the Middlesex County Medical Society on Tuesday, April 20, at 3 p.m., at Staines County Hospital, Ashford, Dr A. G. Signy will speak on "Some Problems in Macrocytic Anaemias" and Dr. D Court on "The Health of Nurses." Visitors, especially members of the American, Canadian, and other oversea Forces now in this country, will be welcome.

A meeting will be held at the Medical Society of London, 11, Chandos Street, London, W.1, on May 5, at 2.30 p.m., with the object of forming an Association of Physical Medicine. All members of the profession who are interested are invited to attend.

At the meeting of the Medical Society for the Study of Venereal Diseases to be held to-day (Saturday, April 17) at 2.30 p.m., at 11, Chandos Street, Cavendish Square, W., Major. Marjorie Bolton, R.A.M.C., will read a paper on the sulphonamide treatment of gonorrhoea in women; and on May 29 Fl. Lieut. J. H. Morton, R.A.F., will discuss infestation by *Trichomonas vaginalis*.

The Royal Victoria Infirmary, Newcastle-upon-Tyne, has sent a circular letter to all medical practitioners in the North-East Region announcing that arrangements have been made for out-patients to be seen by appointment, on the same lines as the system which exists for private consultation. For this purpose an appointments bureau has been established at the Infirmary (telephone No. 21151). Full information is given in the circular. Cases of accident or sudden illness will be treated, as hitherto, at any hour of the day or night. Destitute patients, who have no doctor or no ready means of obtaining one, will be advised and treated according to their needs.

The appointment is announced from Washington of Dr. James A. Crabtree as chief medical officer of the Office of Foreign Relief and Rehabilitation Operations; and three U.S. public health service medical officers have been assigned to North Africa.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there was little change during the week in the trends of infectious diseases, the only fluctuations of any size being rises in the notifications of acute pneumonia 201 cases measles 152, and dysentery 26.

The increase in acute pneumonia was general throughout the country, and the incidence has reverted to the high level of the end of January and beginning of February. The only local rise of any size was that of Staffordshire, 38 cases more.

Only small fluctuations occurred in the county totals of scarlet fever, whooping-cough, and diphtheria: the largest were in Lancashire, where increases of 51, 58, and 18 respectively were reported.

The higher incidence of measles was due to a rise in the South. The largest increases recorded during the week were Suffolk 215, London 177, Surrey 173, Glamorganshire 130, Northants 128, Kent 125, Devon 120, Middlesex 114; and the largest declines were those of Yorks West Riding 172, Warwickshire 169, Yorks East Riding 116, Essex 125, Sussex 111, Bedfordshire 105, Durham 87, Leicestershire 82.

Although the number of cases of dysentery rose by 26, only one local outbreak of any size was reported—Birmingham C.B. 10 cases. The largest of the county totals were Lancashire 14 (Manchester C.B. 6), Surrey 14 (Godstone R.D. 7), London 10, Yorks West Riding 9.

In *Scotland* a further large rise, 80 cases, was recorded in the notifications of measles. The outbreaks in Edinburgh and Glasgow fell by 21 and 24 cases respectively. The notifications of diphtheria went up by 27, while the figures for scarlet fever and whooping-cough dropped by 26 and 29.

In *Eire* typhus has reappeared after an interval of three months: 7 cases were notified in the rural district of Carrick-on-Shannon No. 1, Co. Leitrim. There were 75 cases of whooping-cough, compared with 29 in the preceding week, the rise being due to outbreaks in Co. Waterford, Waterford C.B. 19, Co. Clare, Kilrush R.D. 15, Co. Wexford, Enniscorthy R.D. 15. In Dublin the cases went up from 13 to 18.

Cerebrospinal Fever

The incidence of cerebrospinal fever during the present year has been the lowest for this period since the outbreak of war. The trend of this disease has been steadily on the downgrade since the large outbreak in 1940. The peaks in the early spring have progressively diminished in size and the intervening endemic level has fallen. A comparison of the notifications for the first twelve weeks of the year is:

Week	Average of 1936–9	1940	1941	1942	1943
1	30	53	232	149	88
2	37	107	266	178	94
3	30	144	287	132	89
4	29	184	307	152	111
5	33	299	332	183	106
6	29	406	345	166	121
7	38	557	376	186	100
8	29	585	430	165	101
9	40	617	406	216	92
10	33	603	365	227	86
11	31	541	332	281	93
12	33	476	334	197	104

Quarterly Returns for Northern Ireland

The birth rate for the fourth quarter of 1942 was 21.8 per 1,000 and was 3.5 above the average rate for the December quarters of the five years 1937–41. Infant mortality was 74 per 1,000 births registered and was 1 below the five-year average. The general death rate was 12.8 per 1,000, compared with 13.0 for the average of 1937–41. The number of deaths attributed to the principal epidemic diseases was 139, compared with 196 for the average of the five preceding fourth quarters. Deaths from pulmonary tuberculosis numbered 204, which was the same as the average, but other forms of tuberculosis accounted for 73 deaths—16 above the average. Of the 4,162 deaths registered during the quarter 12.7% were in persons under one year of age and 50% in persons aged 65 and over.

Quarterly Returns for Eire

The birth rate during the fourth quarter of 1942 was 21.2 per 1,000 and was 3.7 above the rate for the December quarter of 1941. The infant mortality rate was 78 per 1,000 registered births, being 4 above the rate for the fourth quarter of 1941. The general death rate was 13.7 per 1,000, an increase of 1.5 on the rate of the December quarter of the preceding year. The principal epidemic diseases accounted for 502 deaths, compared with an average of 336 for the fourth quarters of 1937–41. There were 745 deaths from pulmonary tuberculosis and 175 from other forms of tuberculosis, compared with averages of 589 and 157 for the five preceding fourth quarters.

For the whole of 1942 the birth rate was 22.3 per 1,000, being 3.3 above the rate for 1941. The infant mortality rate was 68 per 1,000 registered births and was 6 lower than in the preceding year. The general death rate was 14.0 per 1,000, being 0.6 below the rate of 1941. The principal epidemic diseases caused 1,639 deaths, or 280 more than in 1941. Deaths from pulmonary tuberculosis were 3,464 and from other forms of tuberculosis 811; the numbers for 1941 were 2,882 and 829.

The Week ending April 3

The notifications in England and Wales during the week included scarlet fever 2,213, whooping-cough 2,078, diphtheria 798, measles 19,568, acute pneumonia 1,494, cerebrospinal fever 108, dysentery 109, paratyphoid 3, typhoid 15. Influenza deaths in the great towns numbered 67.

No 12

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 27.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Diphtheria in the Immunized

Q.—*A child of six was inoculated with 0.2 c.cm. of alum-precipitated diphtheria toxoid. Three weeks after the injection he developed an acute sore throat with a few punctate septic spots on the tonsils. The boy vomited occasionally; the temperature was 103.5° F.; knee-jerks were present, and there was no albuminuria. Diphtheria bacilli were obtained from a throat swab. I should be grateful for answers to the following questions: (1) In the early days of inoculation against diphtheria is the risk of diphtheria infection increased—i.e., during a negative phase? (2) Granted that the two immunization injections have been given, and that a Schick test is negative, what course should a practitioner follow when presented with a case of sore throat from which diphtheria bacilli are isolated—that is, if no typical membrane is present? (3) Is the appearance of the throat in the case of diphtheria in an immunized person different from the ordinary diphtheria throat in the non-immunized?*

A.—(1) There is no convincing evidence that the immediate risk of diphtheria infection is increased by immunization. Many immunologists regret that the phrase "negative phase," in this connexion, ever escaped from the laboratory, where it is of scientific interest. (2) The practitioner without ready facilities for repeat Schick tests and tests for virulence of the bacilli reported as "positive" would be wise to inject antitoxin as a precautionary measure and to keep the child under observation. With the Pope-Parfentjev modern "enzyme-treated" antitoxin the risk of serum-sickness has become minimal. "If a throat is suspicious enough to demand a swab it is suspicious enough to demand antitoxin." Where a recent Schick test, properly carried out, has been negative the sore throat is probably a streptococcal tonsillitis in an immune diphtheria carrier, and one of the sulphonamides should be prescribed. (3) True clinical diphtheria infection in children who have been properly immunized is rare and mostly trivial in its local and general effect, but typical severe infection with sore throat has been reported in people whose immunity is too low.

A Toxic Eruption

Q.—*A man aged 67 has developed vesicles above the ankles in the area of the socks. They are rather large, with inflammation, swelling, and itching (slight) of the skin. They are exactly like a burn of the first degree. What is the name of this condition? Is it pemphigus? There has been frequency of the bladder for some time, with cloudy and acid urine. Alkalis have been taken for this, with resorcin and hexamine at intervals. What would the best treatment for the condition be?*

A.—Symmetrically disposed large vesicles above the ankles in a man aged 67 are most likely due to a toxic condition; if the patient has frequency he may have retention, with overflow, and it would be wise to have his blood urea estimated. The condition may also result from contact with an irritant, such as a liniment applied to a stiff ankle, so that an external factor must be excluded. When this has been done, and the factors likely to produce toxaemia attended to, the local treatment consists in pricking the blisters with a sterile needle and painting the areas with liq. pic. carb. ♏xv, tannic acid gr. x, aq. ad ʒj; and dusting on simple talcum powder.

Irregular Menstruation

Q.—*Irregular menstruation worries many young adults. What can be done to establish a normal menstrual cycle?*

A.—Irregular menstruation in young adults usually takes one of two forms. The more common one these days with so many girls entering the Services and factories is for amenorrhoea to occur. If the previous menstrual history is normal and the patient fit it is advisable to reassure her and do nothing for three or four months. Many patients when reassured menstruate normally soon afterwards. If the menses do not return give intermittent oestrogenic stimulation. 5 mg. stilboestrol daily for 14 days will usually be followed by bleeding. When bleeding ceases give 1 mg. daily for another 14 days, and repeat this for two or three months. If there is any evidence of thyroid deficiency small doses of thyroid, 1 gr. a day, sometimes give dramatic results. The less common type is when periods come too frequently, possibly with heavy losses. These are more difficult to treat. If the pelvis is healthy the best results are likely to be obtained by giving gonadotrophic hormone. Serum gonadotrophin, 200 to 400 units weekly for three or four weeks, should be tried. Between losses iron should be given, but must be discontinued when bleeding occurs. Excessive losses occasionally require curettage and even transfusion. It should be noted that stilboestrol is more likely to cause harm than benefit in this type of case. Good results can be obtained from male hormone, but its use must be carefully controlled and is better not adopted in general practice.

Treatment of Disseminated Sclerosis

Q.—*Which of the suggested treatments for disseminated sclerosis has the best justification—arsenic, liver injections, vitamin A therapy, etc.?*

A.—Organic arsenicals are widely used to-day in dosages similar to those employed in treating syphilis. It cannot be said that any form of treatment has a specific or certain effect upon disseminated sclerosis, but one gains the impression that cases treated regularly with organic arsenic over a long period progress more favourably than others. Give courses of weekly intravenous injections totalling 5 g. N.A.B., with two-monthly intervals between courses, over a period of 12 to 18 months. Each course should consist of the following weekly injections: 0.15, 0.3, 0.45, 0.6, 0.75, 0.9, 0.9 g. Patients with disseminated sclerosis are particularly liable to sharp febrile reactions after arsenic injections, which should therefore be small to begin with. There is no evidence that liver therapy has any effect and vitamin extracts are of no direct benefit. It is very important in this disease to keep general health and resistance as high as possible to reduce the risk of exacerbations. These are often provoked by intercurrent illness or injury. Vitamin extracts may play their part in this general treatment. In addition to organic arsenic, colloidal gold injections are often used, but with inconclusive results.

INCOME TAX

Housing on Transfer

"DELTA" rented a house when taking up E.M.S. duty at a hospital in 1939. In 1941 he was transferred to another locality, which "necessitated taking a furnished house there," and let the previous house furnished. The authorities claim income tax on the "profit" made on that letting, though owing to the high cost of the furnished house which "Delta" now rents he is at least no better off.

*** There is legal justification for the assessment, as the "profit" is assessable without any deduction for the cost of living elsewhere. (The point was settled by judicial authority in 1912—Wylie *v.* Eccott). The fact that the transfer was compulsory does not assist the taxpayer.

LETTERS, NOTES, ETC.

Enterospasm and Spastic Colitis

Dr. D. M. C. CHURCH (Edinburgh) writes: The answer to the question about enterospasm and colitis (March 27, p. 402) is excellent. I find that if the diet is attended to as suggested a tablespoonful of freshly powdered charcoal taken after the midday and evening meals gives complete relief. Purgatives are forbidden, but if quite essential a small enema containing about a drachm of magnesium trisilicate does no harm.

Treatment of Scabies

Dr. E. D. SPACKMAN (Worthing) writes: As I had a little spare time last evening I picked up the *Journal* for April 3 and the April number of the *Practitioner*. I read carefully Dr. J. R. Graham's article on scabies in the *Journal*, noting his experience in 1,000 cases and his "conclusion" (p. 414): "One treatment with benzyl benzoate will cure over 99% of scabies if efficiently applied. Disinfection of clothing and bedding is unnecessary." Then I opened the *Practitioner*. I read a very detailed article on "Scabies in Children," seven pages, by Dr. Brain, a dermatologist. On p. 236 I read: "Then comes the third essential for success, which is *the disinfection of the clothing*" (the italics are Dr. Brain's, not mine). As the views of two specialists on scabies appear diametrically opposed over the question of clothing disinfection it would be helpful to hear the experience of general practitioners on this matter.

Correction

The strength of the emulsion of benzyl benzoate used for the cases of scabies described by Dr. John R. Graham (April 3, p. 413) was that of the *N.W.F.* emulsion—namely, 25% not 20%.

CEREBROSPINAL FEVER

ANALYSIS OF 3,575 CASE REPORTS, WITH SPECIAL REFERENCE TO SULPHONAMIDE THERAPY

BY

PAUL B. BEESON, M.D.

AND

ETHEL WESTERMAN

(American Red Cross-Harvard Field Hospital Unit)

Many articles have appeared within the past five years showing that sulphonamide therapy has effected a considerable reduction in the number of fatalities due to cerebrospinal fever. These reports, most of which are based on groups of less than a hundred cases, are not in agreement on certain matters, such as the sulphonamide compound of choice, its proper dosage, and the value of serum as an adjuvant to chemotherapy. Such differences in experience with cerebrospinal fever are to be expected, since the disease is notoriously variable in severity and in its effect on persons of different ages. In the present communication an attempt is made to obtain information on some of the points in question by means of an analysis of a large number of case reports.

The study is based on 3,575 reports of cases of cerebrospinal fever which were submitted to the Ministry of Health by more than a hundred widely scattered hospitals of England and Wales during the two-year period June, 1939, to June, 1941. A large proportion of cases (2,738, or 76.6%) occurred during the first six months of 1940. The total number of cases notified in England and Wales during the same six-months period was 9,184. The reports under consideration appear to be a representative sample from the general population, urban and rural. Standard forms drawn up and distributed by the Ministry of Health were used for reporting. Nearly 4,000 case reports were submitted, but a number were excluded because of doubt as to correctness of diagnosis. In more than 90% of the 3,575 cases finally accepted for analysis the diagnosis had been confirmed bacteriologically. Some reports were incomplete with respect to certain particulars, such as age, sex, or details of therapy; for this reason several sections of the study are based on smaller numbers of cases.

Age and Sex Incidence

Age.—It is well known that cerebrospinal fever tends to occur most frequently in young persons. In the present series 45.5% of the patients were children under 15 years of age (see Table I). The preponderance in young persons is not as great in this series as in some other large groups of cases. For example, in the Detroit epidemic of 1928-31, 60% of the patients were children under 15 years old (Gordon, 1932), while in the German epidemic, 1905-7, approximately 80% were in this age group (German Health Reports, quoted by Ledingham and Arkwright, 1912).

TABLE I.—*Age Distribution: 3,557 Cases**

Age in Years	Cases	Percentage of Total	Age in Years	Cases	Percentage of Total
0	255	7·13	25–29	306	8·55
1	209	5·84	30–34	243	6·73
2	205	5·73	35–39	181	5·06
3	164	4·58	40–44	130	3·63
4	127	3·55	45–49	92	2·57
5–9	358	10 01	50–54	80	2·23
10–14	300	8·39	55–59	75	2 09
15–19	426	11·91	Over 60	76	2·12
20–24	330	9·23			

* 18 cases in which age of patient was not specified were not included in this table.

Sex.—The ratio of males to females in the whole group was 6 to 4 (59.5% and 40.5%). The sex distribution at different ages (Table II) shows more males than females in every age group below 50 years. The highest ratio of males to females was in persons between the ages of 20 and 34 years. This may be attributable in part to the large numbers of young men recently entering military service, in which the incidence of meningococcal infections is regularly high. On the other hand, the sex distribution closely resembles that found in the Detroit epidemic, which involved a civilian population (Gordon, 1932).

TABLE II.—*Fatality Rate by Age Groups in Males and Females: 3,555 Cases**

Age in Years	Males			Females		
	Cases	Deaths	Case Fatality Rate (%)	Cases	Deaths	Case Fatality Rate (%)
0	154	51	33·11	101	28	27 62
1	126	26	20 63	83	17	20 48
2	129	21	16·27	76	19	22 36

Over 60	33	19	57·57	43	24	55 81
Total	2,120	310	14 62	1,435	256	17 84

* Not included in this table: 18 cases in which age was not stated, 2 cases in which sex was not stated.

Case Fatality

Among the 3,575 patients 570 deaths occurred, a fatality rate of 15.94%. This figure is lower than that for all notified cases in England and Wales during 1940 (2,584 deaths in 12,767 cases, a rate of 20.24%), although the general fatality rate is probably falsely high, since certification of deaths from any disease is likely to be more complete than notification of cases.

Fatality in Relation to Age.—It has long been appreciated that the prognosis of cerebrospinal fever depends to a considerable extent on the age of the patient. The fatality is usually highest in infants under 1 year old and in adults over 40. The present data show that the use of sulphonamides has not lessened the influence of age; in fact, the age of the patient is perhaps more significant now than before (Fig. 1). Results of treatment were poorest at the extremes of life, and best in persons of the second and third decades. The age group 15–19 years had the lowest rate (5.6%); in infants under 1 year of age it was nearly six times as great (31%); while in persons over 60 years of age it was ten times as high (56.6%).

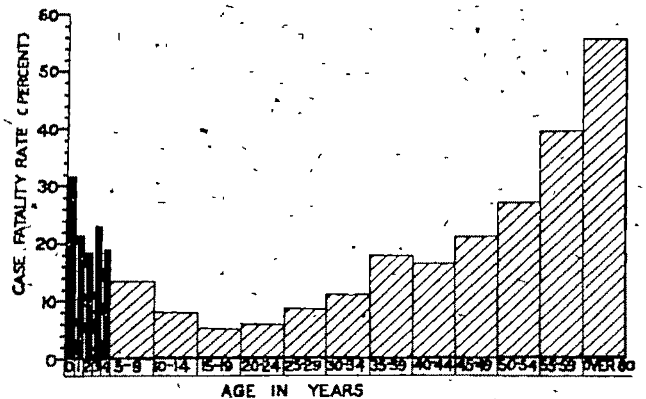

Fig. 1.—Cerebrospinal fever case fatality rate according to age; 3,557 cases.

Fatality in Relation to Sex.—Fatality was greater among females (17.8%) than males (14.6%). Comparing rates for both sexes at different ages (Table II), the lower average rate for all males can be seen to be due in part to the high proportion of males at ages 20 to 34, a time of life at which the probability of recovery from cerebrospinal fever is greatest. When adjusted for age the average rates for the two sexes do not differ significantly.

Severity and Complications

A request for the attending physician's estimate of clinical severity was included in the forms used in this survey. On the basis of these estimates cases were divided into three grades—mild, moderate, and severe. Of the 3,308 cases in which this classification was possible, 1,568 (47.4%) were severe, 1,297 (39.2%) were moderate, and only 443 (13.4%) were mild.

Cranial nerve paralysis, arthritis, and deafness were the commonest complications. The cranial nerves most often involved were the third, fourth, sixth, and seventh, leading to strabismus or facial weakness. Table III contains all complications mentioned in the reports. Conditions which had disappeared or were terminating at the time the patient was discharged from hospital are classed as transient; those still present at the time of discharge are designated permanent. While this undoubtedly includes the common complications of cerebrospinal fever, with some indication of their relative frequency, the actual incidence is probably greater, owing to the fact that the forms used did not contain a specific request for enumeration of complications. No indication of the incidence of late sequelae could be obtained from this material.

Table III.—*Complications Noted in Hospital: 3,005 Non-fatal Cases*

Complication	No. of Cases	Duration		
		Transient	Permanent	Not Stated

Pericarditis	1	1	0	0

Cases terminating Fatally within 24 Hours of Admission to Hospital

For the purpose of evaluating therapeutic measures patients who died within 24 hours of admission to hospital were separated from those whose death took place after more than one day of hospital treatment. Of all fatalities 217, or 38%, were in the less-than-24-hour group. Their incidence according to age is shown in Table IV. There does not appear to have been a significant grouping at any period of life. Study of the reports leads to the conclusion that in most instances death was attributable to severity of the disease rather than to delay in starting treatment.

Table IV.—*Fatalities within 24 Hours of Admission to Hospital, by Age Groups: 217 Cases*

Age	Total Deaths	Death within 24 Hours	
		Number	Per Cent.

Specific Therapy

Sulphonamides

In comparing various factors in sulphonamide therapy the procedure in this analysis has been to consider only those patients who survived 24 hours or more after admission to hospital. This arbitrary division has been made on the assumption that a patient who survived for less than 24 hours after the beginning of treatment did not constitute a fair test subject.

Comparison of Various Sulphonamides.—Five different sulphonamide drugs were employed—sulphapyridine, sulphanilamide, sulphathiazole, soluseptasine, and proseptasine. The frequency with which they were used is shown in Table V, together with the corresponding case fatality rates. Sulphapyridine (M & B 693) was by far the most popular drug. It alone was used in 86.6% of the cases, and in combination with one of the other sulphonamides in an additional 200 instances, or 95% of the total. Sulphanilamide and sulphathiazole were the only other compounds used often enough to warrant comparison. The fatality rate for patients treated with sulphathiazole, alone or in combination, was the lowest—2.5% for 80 cases, treated in one hospital. With sulphanilamide, alone or in combination, there were 18 deaths among 227 cases, a fatality rate of 7.9%. With sulphapyridine, alone or in combination, there were 222 deaths in 2,321 cases, a fatality rate of 9.6%. No conclusion should be drawn from these figures, because the numbers of persons treated with sulphathiazole and sulphanilamide were too small to justify comparison by age groups.

Table V.—*Comparative Fatality Rates with Different Sulphonamide Compounds: 2,455 Cases**

Sulphonamides	Number of Cases	Number of Deaths	Fatality Rate (%)
Sulphapyridine	2,121	206	9·71
Sulphanilamide	90	7	7·78
Sulphathiazole	38	2	5·26
Sulphapyridine and sulphanilamide ..	136	11	8·09
„ „ sulphathiazole ..	42	0	0
„ „ soluseptasine ..	20	5	25·00
„ „ proseptasine ..	1	0	0
Soluseptasine and proseptasine .	1	1	100·00
Sulphapyridine, sulphanilamide, and soluseptasine	1	0	0
Not stated	5	1	20·00
Total	2,455	233	9·49

* Not included in this table: 900 cases treated with serum and sulphonamides; 201 fatalities in which death occurred within 24 hours of admission to hospital; 15 patients who received neither sulphonamides nor serum; 3 patients who received serum only.

Dosage.—Banks (1939) has recommended the following schedule of dosage in the treatment of cerebrospinal fever:

Age period in years (inclusive) ..	0–1	2–4	5–9	10–14	15 and over
Daily amount in grammes ..	3	4½	6	7½	9

But, he added, "there is evidence that lower dosage of sulphapyridine will often be successful." The Ministry of Health adopted Banks's suggestions in their Memorandum (1940). Some persons have criticized this dosage as too large and have claimed that equal results can be obtained with about two-thirds as much (Willcox and Cutts, 1941). In the present analysis an attempt has been made to compare results obtained when the amounts used were less than those of Banks with results obtained when sulphonamides had been given in a quantity equal to or greater than that recommended. Any administration of drug previous to admission of the patient to hospital was disregarded, because the data were seldom complete. The division of cases into the two groups was made on the basis of dosage of sulphonamide during the first 24 hours after admission to hospital. Statistically (Table VI), it could not be shown that the results were better in cases treated strictly according to Banks's schedule than in cases treated somewhat less intensively.

TABLE VI.—*Comparison of Dosage in Recovered and Fatal Cases: 3,123 Cases**

Age Group	Percentage who received Dosage Equal to or Greater than Banks's Schedule	
	Recovered	Died
0	52·7	51·8
1	66·7	70·9
2	37·6	56·6
3	53·7	80·9
4	50·0	70·0

10–14	50·8	38·5
15–19	51·9	80·0
20–24	54·5	55·5
25–29	53·9	35·7
30–34	54·5	61·1
35–39	53·9	38·1
40–44	50·0	45·5
45–49	50·0	75·0
50–54	50·9	45·5
55–59	46·5	62·5
Over 60	45·2	59·4

* Not included in this table: 233 cases in which the data were inadequate; 201 cases in which death occurred within 24 hours of admission; 19 cases in which chemotherapy was not used.

Duration of Sulphonamide Therapy.—Great variation was found in the length of time chemotherapy was continued. The number of days of sulphonamide therapy in the non-fatal cases is shown in Table VII. The average length of treatment was eight days. Therapy was discontinued in 200 or more cases on each day of treatment from the fourth to tenth days, 73% of the cases falling into this period. There was little mention of necessity for resumption of treatment because of too early discontinuance.

TABLE VII.—*Duration of Chemotherapy: 3,005 Non-fatal Cases*

Duration of Chemotherapy (Days)	Number of Cases	Percentage of Total	Duration of Chemotherapy (Days)	Number of Cases	Percentage of Total
1	1	4·4	13 and 14	109	3·6
2	25		15 ,, 16	51	
3	106		17–20	49	3·3

9	347	11·2	57	1	
10	249	8·3	Not stated	220	7·3
11 and 12	201	6·7			

Relation of Duration of Disease before the Beginning of Therapy to the Final Outcome.—A delay in admission to hospital does not appear to have been a prime factor in determining the outcome, since patients who recovered did not, on the average, begin treatment any earlier than patients who died. Patients who died within the succeeding 24 hours (Table VIII) were, in general, admitted earlier in the course of their disease than those who recovered or those whose death took place 24 hours or more after admission. One must conclude, therefore, that early institution of chemotherapy is not in itself sufficient to prevent death in certain cases of cerebrospinal fever. This does not, of course, lessen the desirability of beginning treatment as early as possible; it simply indicates that such factors as virulence of the infecting agent and resistance of the host are still of the greatest importance, even with the benefit of sulphonamide therapy.

TABLE VIII.—*Day of Disease on which Chemotherapy was Instituted: 3,556 Cases**

Day of Disease which Therapy was Instituted	Recovered Cases		Death within 24 Hours of Admission		Death more than 24 Hours after Admission	
	Cases	Percentage of this Group under Treatment	Cases	Percentage of this Group under Treatment	Cases	Percentage of this Group under Treatment

* Not included in this table: 16 cases in which no treatment was given, 3 cases in which serum therapy alone was used

Serum

Combined Treatment with Sulphonamide.—In all, 965 patients received serum in addition to sulphonamide therapy. Including patients who died within 24 hours of admission to hospital there were 181 deaths—a fatality of 18.8%. Among 2,591 patients treated with the drug alone there were 389 deaths—a rate of 14.3%. After adjustment for age the difference between these two rates is highly significant. Fig. 2 shows that in nearly every age group the results with combined drug and serum therapy were less satisfactory than those achieved with the drug alone. Several factors were studied in an effort to discover why the mortality was greater in serum-treated cases.

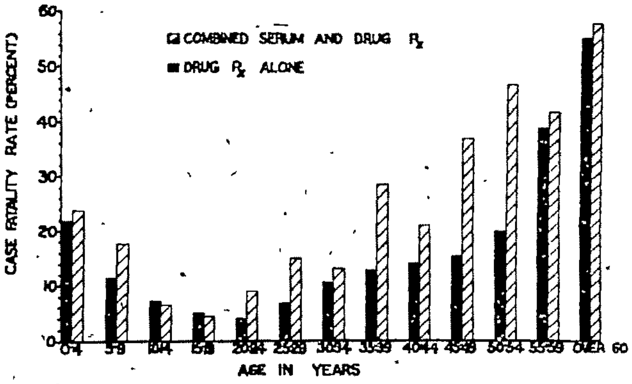

FIG. 2.—Cerebrospinal fever; 3,557 cases. Comparative case fatality rates.

(*a*) *Comparison of Types of Antiserum.*—Two types of antiserum were used—antimeningococcus serum and meningococcus antitoxin. The rates for the two show little difference (Table IX).

TABLE IX.—*Comparative Fatality Rates with Different Types of Serum: 965 Cases*

Type of Serum	Cases	Deaths	Case Fatality Rate (%)
Antimeningococcus serum ..	370	63	17·02
Meningococcus antitoxin ..	124	22	17·74
Antimeningococcus serum and meningococcus antitoxin ..	16	4	25·00
Not specified	455	92	20·22
Total	965	181	18·75

(*b*) *Route of Administration of Serum.*—This may be significant (Table X) in that the fatality rate was somewhat higher in patients who received serum intravenously.

TABLE X.—*Comparative Fatality Rates with Different Routes of Serum Administration : 895 Cases**

Route of Administration	Number of Cases Treated	Number of Fatalities	Fatality Rate (%)
Intramuscular only	375	60	16·00
Intrathecal only	200	39	19·50
Intravenous only	101	23	22·77
Intramuscular and intrathecal	126	21	16·66
Intramuscular and intravenous	70	23	32·85
Intrathecal and intravenous	17	4	23·52
Intramuscular, intrathecal, and intravenous	6	3	50·00
Total	895	173	19·33

* Not included in this table: 70 cases in which route of serum administration was not specified.

(*c*) *Dosage of Sulphonamide in Patients receiving Combined Therapy.*—The higher mortality in patients treated with serum might conceivably have been due to a tendency to administer insufficient quantities of the drug. This was not borne out by analysis, since the percentage of patients who received sulphonamides on a scale equal to or greater than that of Banks was almost exactly the same in serum-treated cases as in those treated with sulphonamide alone (57.5% and 58.1% respectively).

(*d*) *Serum Administration where Drug Therapy had Failed.*—Of patients receiving serum 88% were treated on the first hospital day It is not likely, therefore, that serum administration had often been used as a last resource where drug therapy appeared to be without result.

(*e*) *Use of Serum for the More Severe Cases.*—One factor which probably played some part in the greater fatality rate for serum-treated patients was disclosed by comparing the clinical severity of the two series. Of cases which received the combined serum-and-drug therapy 56% were rated as severe, and only 6% as mild; while of the cases treated with the drug alone 38.8% were rated as severe and 14.8% as mild.

Discussion

This large group of patients, including both sexes, all ages. and treated in more than a hundred different hospitals, adds further weight to the previously recognized efficacy of the sulphonamides in the treatment of cerebrospinal fever.

The age of the patient is a significant factor in determining the final outcome; fatality rates range from as low as 5.6% in young adults to as high as 56.6% in persons over 60. In view of this the evaluation of any therapeutic procedure must give careful consideration to the age grouping of the population concerned. A number of recent articles on the treatment of cerebrospinal fever have been based on experience in military populations. Results with such patients of a favourable age group would naturally be better than results obtained for a general population.

When the present analysis was undertaken opportunity was anticipated for comparison of the efficacy of various sulphonamide preparations. It was found, however, that sulphapyridine had been used almost to the exclusion of all others, so that statistically significant comparisons for the several drugs by age groups could not be made. The gross fatality rate with sulphapyridine was higher than that with either sulphanilamide or sulphathiazole. Information was likewise desired on the optimum dosage of sulphonamides, in view of the controversy about the need for a dosage as large as that recommended by Banks. In this analysis it could not be shown that deaths were less frequent among patients treated according to Banks's schedule. Hundreds of patients recovered satisfactorily when one-half to two-thirds the recommended amounts were administered; and conversely, 58.4% of the patients who died had received a dosage equal to or greater than the schedule of Banks. There were, however, some few fatal cases when the amount of drug given was less than one-half that recommended by Banks, and it may well be that in some instances the administration of a greater quantity of drug would have sufficed to turn the tide.

Patients treated with serum in addition to sulphonamide had a higher fatality rate than those treated with drug alone. The only determinable factor was that a higher proportion of cases treated with serum were graded as severe. On the other hand, this study furnishes no evidence that serum therapy is beneficial when combined with chemotherapy in cerebrospinal fever. That the use of serum actually did harm cannot be stated with certainty. In this connexion the recent study of Plummer *et al.* (1941) on the comparable problem in pneumococcal pneumonia is of interest. In an alternate series of cases a slightly higher fatality rate was observed in a group of patients receiving serum in addition to sulphonamide than in patients treated with drug alone. This is especially noteworthy in view of the proved efficacy of serum therapy in pneumonia.

Statistically, the results were as good when therapy was begun comparatively late in the course of the disease as when it was begun earlier. This is probably due to the fact that when therapy was begun later in the disease it was on the whole in the milder cases; while treatment was begun earlier when the clinical condition was so alarming as to necessitate early removal to hospital.

Summary and Conclusions

The present report is an analysis of data on cerebrospinal fever which had been collected by the Ministry of Health. The source of the information was a group of 3,575 case reports submitted from more than a hundred hospitals in England and Wales during a two-year period between 1939 and 1941. All but 19 patients were treated with sulphonamides, and 965 of them received some form of specific serum therapy.

The disease occurred most often in infants and young children, 45.5% of the patients being under 15 years of age. The ratio of males to females was 6 to 4.

The fatality rate for all patients was 15.94%; it was greatest at the extremes of life and least in the 15–19-years age group. Of the deaths in the series 38% occurred within 24 hours of the time of admission to hospital.

The most frequent complications were cranial nerve paralysis, arthritis, and deafness.

The case fatality rate in 2,591 cases in which sulphonamides alone were used was 14.3%. In an additional 965 cases, in which serum treatment was combined with chemotherapy, the fatality rate was 18.8%. The poorer result was probably due in part to the fact that serum was administered to more severely ill patients. On the other hand, there is no indication from this study that the administration of serum as an adjuvant to sulphonamide therapy is beneficial.

In the treatment with sulphonamides a considerable variation appears to be possible in such matters as dosage and duration of therapy without noticeable effect on the fatality rate.

Statistically the results were about the same whether chemotherapy was begun early or comparatively late in the course of the disease. This can be attributed to the fact that severe cases tend to be sent to hospital sooner than mild cases.

The host factor, particularly the age of the patient, is of distinct importance in determining the outcome of meningococcal infection, even with the aid of sulphonamide therapy.

Measures taken to control the domestic mosquito in Kenya have been such that it is now improbable that yellow fever if introduced into the Colony could establish itself or assume epidemic form in any urban centre. The latest annual report of the Medical Department for the Colony and Protectorate of Kenya describes the work and also the steps taken to ensure control of mosquito breeding on all steamships and dhows entering the port of Mombasa. An inoculation campaign was started in April, 1941, and by the end of the year all the inhabitants of Mombasa and of the country between Mombasa and the Tanganyika boundary had been inoculated. In addition many persons who were likely to travel either to Uganda or to India were inoculated in up-country towns. Altogether something like £20,000 was spent during the year on these preventive measures.

CHEMOTHERAPY AND SEROTHERAPY IN CEREBROSPINAL (MENINGOCOCCAL) MENINGITIS

AN ANALYSIS OF 3,206 CASE REPORTS

BY
A. A. JUBB, M.D., D.Sc.
A Medical Officer of the Ministry of Health

Cerebrospinal (meningococcal) meningitis, usually known as cerebrospinal fever, became compulsorily notifiable throughout England and Wales on Sept. 1, 1912; previous to that date the disease had been notifiable only in certain districts. The prevalence from 1913 onwards is shown in the following abridged table of notifications, with deaths in parentheses:

TABLE I

1913	1914	1915	Av. 1916–20	Av. 1921–5	Av. 1926–30	Av. 1931–5	1936	1937	1938	1939	1940
305 (332)	315 (194)	3,712 (2,203)	1,000 (908)	371 (343)	516 (490)	1,593 (988)	994 (635)	1,140 (698)	1,288 (652)	1,500 (514)	12,771 (2,584)

Between the peak years 1915 and 1940 the smallest annual number of notifications was 301 in 1923, and the largest 2,157 in 1931. The prevalence remained at a low level from 1920 to 1929, when it began to rise until 1931-2. A decrease thereafter was followed by a steady increase, and in the Chief Medical Officer's Annual Report for 1938 the statement was made that as since the epidemic period in 1931-3 the number of notifications had not fallen to so low a point as after the 1915-17 epidemic, and as the number of Group I infections appeared to be increasing, the probability that we were approaching another period of epidemic prevalence could not be disregarded. The suspicion was confirmed in 1940, and to a degree beyond expectation.

It is possible, however, that in the second and third quinquennia in the table the annual numbers of notifications from which the averages are derived do not represent the true prevalence, for it is precisely in those years of minimal notification that the deaths were proportionately high and in some years even exceeded notifications. On the other hand, as was suggested in a previous Annual Report, it may be that in years of high prevalence, when medical practitioners are on the look-out for the disease, a larger proportion is notified than in years of low prevalence, when cases occur sporadically and are more easily overlooked. Also, as pointed out by Reece (1917), in times of prevalence cases of anomalous disease are more likely to be attributed to cerebrospinal fever than are genuine cases to be overlooked. Probably, then, in the years under review the deaths and not the notifications would be the proper gauge of prevalence.

Fatality Rate.—In the light of these views the fatality rates from 1913 to 1930 can only be approximate. Nevertheless, two conclusions can now be formed: first, that, owing to the almost invariable recourse to bacteriological aid in diagnosis, notification has become more trustworthy as an index of prevalence in recent years; secondly, that there has of late been a steady and real decline in fatality. For instance, in the period 1927-34, comprising four years of low prevalence succeeded by four of high, the average fatality of the first four years was 95% and of the second four 61%. Even allowing that the former figure may be too large through being related to a period of under-notification and the latter figure too small on account of the opposite reason, there is still room to believe that decline took place and, further, to regard a contemporary improvement in the administration of antimeningococcus serum as a factor in the decline. Again, in the years 1935-9 as the annual numbers of notifications increased so the fatality rates decreased, being successively 69.8, 63.8, 61.2, 50.6, and 34.2. The conspicuous drop in the last two years was due to the introduction of the drugs of the sulphonamide series in the treatment of cerebrospinal fever.

Distribution.—In the period 1913-39 the disease was widely spread, here and there assuming the character of epidemicity, as in the West Riding of Yorkshire in 1931-2, the counties of Lancaster, Durham, Derby, and Nottingham in 1932, and in Wrexham district in 1939.

Prevalence in 1940.—The alert was sounded early. In the second week in January the number of notifications rose from 53 to 107, and in the first nine weeks of the year the numbers were successively 53, 107, 144, 184, 299, 406, 557, 585, and 617. From the ninth week (ended March 2) they declined irregularly to 106 in the first week of September. Thenceforward there was a rise, which continued with slight remissions to the end of the year and into 1941 to a maximum of 406 in the week ended Feb. 22.

Distribution in 1940.—The disease prevailed impartially throughout the country; no county in England or Wales escaped, and there were no "dramatic local outbursts." London, which in 1915 suffered severely in proportion to the rest of the country, in 1940 returned only 880 notifications out of the total of 12,771. No doubt this was due to the absence, through evacuation, of a substantial proportion of young persons—those, in fact, in the most susceptible age groups. At the peak of the prevalence (week ended March 2) sixteen counties returned 15 or more notifications, the highest being Lancaster 52, Southampton 51, and Glamorgan 37.

Character of the Disease.—This was of the usual severity. Quite 60% of the case reports analysed below had been noted by the physicians in charge as severe or very severe, and fulminating cases unresponsive to the promptest treatment were not rare. The low fatality rate for the year—20.2%—cannot therefore be discounted by any suggestion that the disease was of a milder order than formerly.

Serum Treatment

In 1930 it became apparent that the results of serum treatment were not proving so satisfactory as those obtained, for instance, among military cases in 1917-18. It was suggested that the cause was that the serum available had been prepared from old strains of meningococcus or strains isolated in interpandemic times, and so might lack antibodies to the organisms responsible for the current outbreak. Another suggestion, advanced by Gordon (1920), was that the serum was deficient in anti-endotoxin. Arrangements were therefore made by the Ministry in 1931 whereby manufacturers of serum were provided with strains of meningococcus procured from current cases of the disease, and reports on the results of treatment by this new "current" serum were invited from medical officers of health, hospital medical officers, and medical practitioners (Reports on Public Health and Medical Subjects, No. 65). This was followed in 1932 by the issue of a *Memorandum to Medical Officers of Health* urging the prompt administration and repetition of adequate doses of serum. From an analysis of the reports received at the Ministry by Dr. E. L. Sturdee in the four years 1931-4 the following figures were extracted. In 382 cases untreated by intrathecal injections of the current antimeningococcus serum the fatality was 61.8% (Sturdee, 1936). In 2,279 cases treated by intrathecal injections of the current serum the fatality was 36.6%. Of the 2,279 cases, 988 that were treated with the current serum on the lines of the recommendations in the Memorandum gave a fatality of 27.9%. Of these 2,279 cases the ages were known in 2,274, and among these the fatality was as follows.

Chemotherapy

In 1935, when prontosil was introduced, a new era dawned in the fight against microbic disease. From prontosil was derived sulphanilamide, and when it was found that prontosil was partly converted in the body into sulphanilamide and also that it passed more slowly from the blood into the cerebrospinal fluid than sulphanilamide the latter became the drug of choice. Banks (1938) reported his results of treatment with serum alone, with serum and sulphanilamide, and with sulphanilamide alone. In 38 cases treated with large doses of serum intravenously and intrathecally the fatality was 16%; the method was relatively difficult and laborious, and the nursing complicated for several days. In 59 cases treated with both serum and sulphanilamide the fatality was 11.8%; recovery was very rapid and the nursing relatively easy. In 16 selected cases of favourable age-grouping treated with sulphanilamide alone there were 15 rapid recoveries. But Whitby (1938) found that another of the sulphonamide derivatives labelled sulphapyridine (M & B 693) was more effective against the pneumococcus than sulphanilamide and equally potent against the meningococcus, and also was less toxic to the patient. This was a great advance, as sulphapyridine can be promptly administered to a case of purulent meningitis while the bacteriological report as to pneumococcal or meningococcal origin is awaited. Banks (1939), reporting on further experience with serum, sulphanilamide, and sulphapyridine, stated that there was no evidence in favour of auxiliary treatment with serum, that sulphanilamide must be given in doses high enough to maintain a certain concentration of the drug in the cerebrospinal fluid for eight or nine days, but that a smaller dosage of sulphapyridine might prove to be successful and that the oral route could be used throughout in most cases.

In consequence of the encouraging results obtained by chemotherapy the Ministry issued in March, 1940, a Memorandum (234/Med.) briefly summarizing the modern views on the treatment of cerebrospinal fever, and giving an account of the dosage and procedure recommended by Banks. The Memorandum also stated that although there appeared to be no convincing clinical evidence that the use of serum was necessary, even as an adjuvant to chemotherapy conducted on the lines given in the Memorandum, nevertheless some recent animal experiments suggested that better results might be obtained by combining the two forms of treatment. Thus, though there was general agreement that Group I and Group II meningococci were equally susceptible to sulphanilamide or sulphapyridine and that the use of these drugs marked a great advance in the treatment of cerebrospinal fever, it was uncertain whether the combined use of either of the drugs with serum was preferable to the use of the drug alone. Jordan *et al.* (1940) obtained far better results when either immune serum or antitoxin was combined with sulphapyridine. Harries (1940) combined the drug treatment with antitoxin in severe cases only. Williams and Brinton (1940), following the practice of Banks, treated 45 consecutive cases with sulphapyridine alone; all the cases recovered and remained free from sequels. These cases, however, were among very fit adults, presumably in favourable age groups.

To secure information on the results of treatment during the high prevalence of cerebrospinal fever in 1940 the Ministry sent in April of that year a letter to the medical officers of health of certain large boroughs throughout the country requesting particulars of cases treated in hospital since the beginning of the year. A form for each case was provided showing the nature of the particulars desired; these included the name of the drug and the amount and hour day by day of each dose of the drug, and of serum if used. The response from medical officers of health and medical officers in charge of isolation and other hospitals was generous, and it is gratefully acknowledged. More than 60 hospitals contributed.

In estimating the fatality rate in a large series of cases treated by serum, Sturdee (1936) excluded deaths due to intercurrent disease or occurring within 24 hours of the first administration of serum. In the present analysis, though serum was not given alone, all cases (approximately 130) were excluded that did not survive more than 24 hours after admission to hospital; this seemed equitable in comparing the results of the methods of treatment—chemotherapy combined with serum, and chemotherapy alone. The total number of cases for analysis, then, was 3,206; of these 849 were treated by the combined method and 2,357 by chemotherapy alone, and the fatality rates of these two classes are given in Tables III and IV.

The antimeningococcus sera and antitoxins used were designated "Burroughs Wellcome and Co.," "Parke, Davis and Co.," "Lister," "Lilly," "Mulford," "Sharp and Dohme," "Lederle," and "New York State." Most of the cases in Table III were treated by sulphapyridine orally and polyvalent serum intrathecally. Occasionally in the treatment of a case the sequence of oral administration was interrupted by parenteral injections of sulphapyridine (soluble M & B 693) or of soluseptasine (a sulphonamide). In the same manner changes were made to sulphonamide (? sulphanilamide) in 7 cases, prontosil in 3, and sulphathiazole (thiazamide) in 3, and in 11 cases sulphonamide (? sulphanilamide) alone was combined with the serum.

Group I serum was given in 29 cases, and Group II serum in 2 cases, in addition to polyvalent serum. In 85 cases meningococcus antitoxin was given, mainly instead of, and sometimes in addition to, polyvalent serum; the use of antitoxin was confined to one or two hospitals. Meningococcus vaccine was administered in 3 cases.

The drug most often employed in Table IV was sulphapyridine, usually by the mouth and sometimes, in addition, intramuscularly or intravenously; sulphanilamide, soluseptasine, and sulphathiazole were also used, but not often enough for separate analysis of effect in treatment.

The salient points in Table III are: (*a*) the low fatality rate for males in age group 15–25; (*b*) the nearly equal sex fatality for all ages, 13.4 and 14.2; (*c*) the low total fatality rate of 13.8; (*d*) the almost unbroken curve of the age-group fatality, falling from infancy to adolescence and then rising to old age. We have no figures of the same age groups to consult, but this was in general the curve in former times.

Table IV, in comparison with Table III, presents a more regular curve of fatality, from infancy downwards to adolescence and rising to old age; and, except in the age groups 3–4 and 65 and over, the fatality rates are substantially lower than in Table III. The fatality at all ages of cases treated by chemotherapy alone was 9.2%, as contrasted with 13.8% among cases treated by chemotherapy combined with serum. In Table IV the very low rate—2.4%—in the age group 15–25 is particularly notable.

Presence of Meningococcus

It is satisfactory to record that out of the total of 3,206 cases the cerebrospinal fluid was examined for the meningococcus in 2,993 cases (93%), with a positive result in 2,727 (91%). The remaining 9% and the 213 cases in which there was no mention of examination were considered by the physicians in charge to be clinically beyond doubt. Of the 849 cases treated by chemotherapy plus serum the meningococcus was sought in 785 cases (93%) and found in 744 (94%). The corresponding figures for the 2,357 chemotherapy cases were 2,204 (90%) and 1,983 (90%). The difference between the two classes in the percentages of search and success is not large enough to have a significance relative to the difference in their fatality rates, and it does not appear that the classes differed in the severity of their cases.

Meningococcal Groups

Brinton (1941) says that those who have had most experience of chemotherapy maintain that it has rendered treatment by serum as obsolete as routine spinal drainage. It was noted above that Group I serum was given in 29 cases, and Group II serum in 2 cases, *in addition to* polyvalent serum and chemotherapy. This proportion in 849 cases does not suggest that much reliance was placed on group sera, and perhaps we shall see group identification falling into desuetude. It is of special value, therefore, to have the opportunity of summarizing here the information gained from what may be the last large-scale inquiry into the incidence and distribution of the meningococcal groups.

Among the 849 chemotherapy-plus-serum cases (Table III) grouping was successful in 189, giving 172 Group I and 17 Group II—a proportion respectively of 91% and 9%. Among the 2,357 cases treated by chemotherapy alone (Table IV) grouping was successful in 489, giving 440 Group I and 47 Group II—a proportion respectively of 90% and 10%. Therefore, so far as was ascertained, the grouping in the two classes of treatment was practically identical. A few cases were reported either as "aberrant" or as reacting to the sera of both groups.

During the epidemic prevalence in the West Riding of Yorkshire in 1930-2 the presence there of Group I among the cases was reckoned at 94%. Among the 2,279 cases reported upon in the period 1931-4 the group was identified in 555, giving 441 Group I and 114 Group II—80% and 20% respectively. But though the period was one of comparatively high prevalence a large proportion of the strains examined came from non-epidemic areas in which Group II proved to be as common as, and in some even commoner than, Group I. The figures in 1940, coming from so many parts of the country where cerebrospinal fever was prevalent, again suggest that an increase of Group I is a factor in epidemicity, but we cannot define its rank of importance among other factors in 1940, such as the mixing of population, the aggregation of persons of susceptible ages, and the conditions of black-out aggravated by inclement weather.

The distribution of the groups was country-wide, contemporaneous, and collateral. As examples of Group I mention may be made of London, Birmingham, Bootle, Cardiff, Carlisle, Chesterfield, Colchester, Derby, Hull, Kettering, Manchester, Liverpool, Oxford, Norwich, Salford, Sheffield, Shrewsbury, and Sunderland. Group II appeared to be just as widely dispersed; London and most of the large towns referred to reported the presence of both groups.

Table V gives the percentage of Groups I and II found in each age period.

TABLE V

Age Group	Percentage of Meningococcal Group		Percentage of Cases not examined or Inconclusive on Examination
	Group I	Group II	
Under 1 year	18	4	78
1–2 years	24	1	75
2–3 ,, ...	22	4	74
3–4 ,, ...	28	1	71
4–5 ,, ...	16	3	81
5–15 ,, ...	22	3	75
15–25 ,, ...	17	2	81
25–45 ,, ...	16	1	83
45–65 ,, ...	13	2	85
65 and over	7	7	86

Severity of Meningococcal Groups.—It has been questioned whether there is a relation between the kind of meningococcal group and the severity of attack. A sampling of nearly 2,000 of the case reports was made with this point in view. Among the cases that could be termed severe or very severe the proportion of Group I was 19% and of Group II 2%; among the mild and moderately severe cases that of Group I was 18% and of Group II 1%. It will be remembered that the group proportions over all identified cases were 90% and 10%. So in the cases under consideration Group II was at least as severe clinically as Group I.

Fatality of the Groups.—The fatality of Group II, moreover, was higher in all cases taken together; it is shown in Table VI.

TABLE VI

Description	Fatality %	
	Group I	Group II
All identified cases	9·7	12·5
Cases treated by chemotherapy and serum ..	12·2	23·5
Cases treated by chemotherapy alone ..	8·8	8·5

It appears, then, that in the cases reviewed Group II equalled Group I in severity and exceeded it in fatality. Something of this nature was hinted at in the Chief Medical Officer's Annual Report for 1931.

Comments

The aim of the Ministry was the collection of information on the results of treatment by chemotherapy, with reference particularly to the amounts and times of dosage as based on the experience of Banks and others, and embodied in the Memorandum of 1940. Many of the physicians filled up the case reports with exactness, giving the amount and hour of each dose of drug, and of serum if used, and added notes on the course of each case, the character of the attack, the response to treatment, and the occurrence of complications and sequels. Cerebrospinal fever is more deadly than deforming, yet its occasional withering effect on the most precious senses must seem at times only less tragic than death. An inquiry is being made into the occurrence and persistence of sequels and the relation of incidence to dosage. So far it appears probable that dosage was not a factor of great importance; and as to blindness and deafness, it is conceded that an early onset of grave damage to nerve cells may be irreparable by any size of dose in chemotherapy or by any form of treatment whatsoever.

It is desirable that the value of cerebral and lumbar puncture be defined, whether or no the procedure should be reserved for diagnosis. Instances of cisternal and ventricular puncture occur in the case reports, and some physicians performed frequent lumbar puncture for the relief of pressure while others never resorted to it for that purpose. In this connexion the opinion of Williams and Brinton (1940) may be quoted: "Neither the high cerebrospinal fluid pressure nor the absence of artificial drainage prevented the passage of sulphapyridine through the choroid endothelium into the cerebrospinal fluid. It seems that the concentration of sulphapyridine in the cerebrospinal fluid maintains a high level if the normal flow and absorption of fluid is undisturbed by repeated drainage. When adequate doses of sulphapyridine are given the disease can be effectively controlled without therapeutic lumbar puncture."

Another important question is whether the value of intramuscular injections of drugs is great enough to outweigh the risk of abscess and sloughing, and the consequent extra labour in nursing and delay in convalescence.

In no instance among the cases under review was a sulphonamide injected into the theca. An account of two cases of paralysis of the lower limbs following the intrathecal injection of soluble sulphapyridine was published by Hunter (1940), and a group of four cases of myelitis after intrathecal injection of soluseptasine were reported to the Ministry in the same year.

It will be noted that there is a preponderance of males in the age groups 15–25 and 25–45. About 100 have been entered as non-civilians on the case reports, and it is possible that others have not been so identified; the excess of males is not to be regarded as an indication of greater susceptibility but of greater exposure to risk in living conditions due to war. At "all ages" of the cases the fatality rate of the females was higher (12.2%) than that of the males (9.3%). It may be that owing to circumstances a larger proportion of males received prompt treatment.

Summary

The fatality rate in 3,206 cases treated in hospital either by chemotherapy plus serum or by chemotherapy alone, and surviving more than 24 hours after admission, was 10.5%.

The rate in 849 cases treated by chemotherapy plus serum was 13.8%.

The rate in 2,357 cases treated by chemotherapy alone was 9.2%.

In the five years 1936–40 there was a steady decline in the fatality of cerebrospinal fever, the annual rates per cent. being successively 63.8, 61.2, 50.6, 34.2, and 20.2. In a series of cases treated in the period 1931–4 with serum of improved quality and administered suitably the rate was 27.9, but a decrease of the rate for the whole country did not occur until the introduction of chemotherapy; with the wider employment since 1938 of the sulphonamide derivatives the decline has been dramatic. In 1941 the rate was 19.5%, and in the first half of 1942 it was 19.5, as against 19.9 in the corresponding periods in 1940 and 1941. It is possible, therefore, that 1942 will show only a slight further decrease.

A RARE CAUSE OF SEVERE GASTRO-INTESTINAL HAEMORRHAGE

WITH A NOTE ON ANEURYSM OF THE HEPATIC ARTERY

BY

GORDON GORDON-TAYLOR, C.B., O.B.E.

Temporary Surgeon Rear-Admiral; Consulting Surgeon to the Middlesex Hospital

The following case seems to merit publication as a rare cause of haematemesis: aneurysm of the hepatic arterial system is an infrequent condition, this instance constituting the 86th recorded. I am aware, however, of another case, still unpublished, in the National War Collection organized by the Medical Research Council. The present case appears to be the only instance in which anything except ligature of the parent artery has been attempted as a surgical measure. Subsequent bacteriological findings in the blood-clot of the aneurysm doubtless precluded any chance of final success from aneurysmorrhaphy in this particular patient, but in other aneurysms which have a non-infective cause the method can hardly yield results more disastrous than those attending ligation; the difficulties are by no means great, and the method is worth consideration by those who may be confronted with aneurysm of this blood vessel on laparotomy.

Clinical History of Case

A married woman aged 61 was admitted into Middlesex Hospital under my care on June 22, 1938. A history was obtained of two years' indigestion unrelieved by food; there were intermissions between the bouts of severe pain, but there had been continuous epigastric discomfort throughout the whole period. The last and final bout of pain had followed a wholesale dental extraction, and for a fortnight before the patient's admission to hospital there had been persistent severe melaena, punctuated by three sharp attacks of haematemesis, which had brought her haemoglobin at one time down to 30%. A continuous-drip blood transfusion had been employed on several occasions, and on her arrival at hospital her haemoglobin had risen again to 70%, and the red cells numbered 3.6 millions. For a week there was no pain or further haemorrhage; obvious melaena ceased, although the faeces still gave a very strongly positive benzidine and guaiacum reaction. The Wassermann reaction was negative.

On July 1, 1938, the patient was suddenly seized with most violent abdominal pain; she vomited blood and collapsed. A diagnosis of a perforated peptic ulcer and concomitant ulcer-haemorrhage was made, and the abdomen was opened under regional anaesthesia and intravenous skophedal; a blood transfusion was at once begun. No ulcer-perforation was found. The liver, gall-bladder and pylorus were bound together into a pulsating mass; the gall-bladder was much distended and bluish in colour; the duodenum and small intestine contained much blood. The existence of an aneurysm in connexion with the hepatic arterial system was now discernible, but the precise nature of its origin and of any recent change in its condition was not at the moment apparent. A better exposure of the tumour was obtained by removal of the pyloric portion of the stomach and the careful separation of the distended gall-bladder from its hepatic bed, the organ being cautiously stripped downwards and mesially from fundus towards neck; this separation was facilitated by the injection of saline into the subserosa of the gall-bladder and between the wall of the latter and Glisson's capsule. The upper and lower boundaries of the pulsating tumour had now been defined and also mobilized.

The distended gall-bladder was next opened, and was ascertained to be filled with recent blood and also blood-clot; blood was indeed seen issuing into the gall-bladder cavity in a steady stream through a small opening on the mesial aspect of its wall. Bacteriological examination of the blood subsequently revealed the presence of streptococci and a scanty growth of *B. coli. Clostridia welchii* were not present in the gall-bladder contents.

The gall-bladder was now removed, with some recent soft clot on the anterior aspect of the pulsating tumour; a little laminated clot was also dissected away, some haemorrhage taking place the while from the opening in the aneurysm despite efforts to compress the hepatic arterial stem. A considerable "button" of aneurysmal wall was left on the artery and a reconstructive aneurysmorrhaphy was performed, the remains of the sac being sutured in layers. All haemorrhage having been arrested, the abdomen was closed without drainage. Next day the condition of the patient was satisfactory, with a pulse of 88; but she afterwards slowly sank and died 40 hours after operation. The post-mortem examination did not demonstrate any failure in operative technique as responsible for the patient's death.

Necropsy.—The lungs showed marked hypostatic congestion and in parts early bronchopneumonia. The *pericardium* contained 3 oz. of fluid. *Heart muscle* exhibited fatty fibrosis. The abdominal *aorta* and main *arteries* showed advanced atheroma; no evidence of syphilitic striation was observed. The *kidneys* were normal in size; the cortex was thinned, and there was patchy ischaemia, with obliteration of glomeruli. Histology: No changes indicative of a "transfusion kidney"; tubules in kidney rather dilated. Blood urea, 170 mg.; non-protein nitrogen, 125 mg. The *spleen* was packed with red blood cells. The *liver* showed toxic degeneration; portal vein and radicles were normal and healthy. The common bile duct was patent and healthy throughout its length. At the junction of the cystic artery and bifurcation of the hepatic artery, which was buried in a mass of laminated and more recent clot, there appeared a widening and a perforation of the arterial swelling.

The operation had not interfered with the patency of the arterial tree. The high blood urea and non-protein nitrogen suggested renal deficiency as at least a contributory cause of the fatal ending, and the fluid in the pericardium also supported this view. Nevertheless I have repeatedly stressed the disastrous results which attend operations for haematemesis from peptic ulcer undertaken after the first 36 hours; the necessity for operation was imposed upon me in this instance on account of a mistaken diagnosis of perforation. All these untoward circumstances combined to determine the fatal issue.

A NOTE ON HEPATIC ARTERY ANEURYSM

The age incidence of cases of aneurysm of the hepatic artery varies between 10 and 83, the average age in men being 36 and in women 42. Men are affected three times as often as women, and an extrahepatic situation of the aneurysm is also thrice as common as an intrahepatic locale. The tumour is almost always single, but there are 12 examples in the literature of multiple aneurysm of this vessel. In six cases 2 aneurysms coexisted; in three instances 3 aneurysms; in another patient 4; in still another 5 aneurysms. The aneurysmal sac has varied in size from a barley-corn (Rollan) or cherry to a full-term foetal head, the extrahepatic variety being usually larger than the intrahepatic form.

Artery of Origin.—In over 50% the hepatic artery itself was involved, and in one-third of the cases the right branch was implicated; in 10% the left branch was the site of origin. Right and left arteries were both aneurysmal in one patient; the cystic artery was implicated in 3 cases; in one patient (Drascke) an aneurysm was said to have developed on an accessory hepatic artery coming from the superior mesenteric.

Rupture of the Aneurysm.—Of aneurysms of the hepatic artery 80% have first come under observation for rupture, nearly half of these inundating the peritoneal cavity and one-third bursting into the main bile channel, especially the hepatic duct. Seven have eroded the duodenum and 7 the gall-bladder. Only one is said to have burst into the stomach, and one perforated the portal vein. In 4 cases a double rupture occurred, of which two burst into the duodenum and the abdominal cavity; one leaked into gall-bladder and coelom, and one perforated the hepatic as well as the common bile duct.

The clinical triad associated with aneurysm of the hepatic artery are pain, haemorrhage, and jaundice (Malloy and Jason, 1942). The case presented in this communication showed no jaundice, and post-mortem scrutiny failed to reveal any compression of the extrahepatic biliary tract, which indeed during life permitted a steady flow of blood into the duodenum. The blood-flow from the aneurysm along these natural channels must have been free, since no clotting occurred in the bile duct, although clot was present in the backwaters of the distended gall-bladder.

The cause of the aneurysm in this patient seems to have been an infective one; not only was the final illness with its haemorrhagic catastrophe initiated by wholesale dental extraction, but streptococci and a small growth of *B. coli* were obtained from the clot in the gall-bladder and that of the aneurysm wall. A mycotic origin is found to be the most frequent cause of hepatic artery aneurysm; trauma has been impugned in a few cases; syphilis has been found less often than atheroma in these patients. Atheroma was certainly present in the hepatic artery as well as in many other arteries in this present case, but the bacteriology appears to favour an infective origin. The case perhaps constitutes one more reminder of the danger attending wholesale dental extraction in oral sepsis at a single operation.

Treatment

Statistics derived from operations on mankind afford slender grounds for the optimistic pronouncement of an Axis writer (Alessandri) that "when an aneurysm of the hepatic artery is present, we are justified in performing ligature of the trunk of the hepatic artery, with or without the slitting or removal of the sac." The results of ligature of the main artery for aneurysm, indeed, appear to be even worse than those attending ligature of the hepatic artery under other circumstances. The same writer collected 10 cases of ligature of the hepatic artery for conditions other than aneurysm and found a mortality rate of 60%.

On the other hand, 12 arterial ligature operations have been performed for aneurysm of the hepatic artery or its branches, and in 75% of these the patients succumbed; in 2 of the 3 surviving cases (Sudeck; Colmar) there was no certainty that any aneurysm was present. Kehr's case appears to be the only positive success in hepatic artery ligature for aneurysm. Alessandri also collected 18 cases of ligature of the right or left branch of the hepatic artery for non-aneurysmal conditions; the mortality was 40%, and the fatal cases almost always revealed necrosis of the corresponding liver lobe.

Any confidence in the successful issue of a ligature of the hepatic artery must be begotten of a pious hope that some aberrant hepatic artery may supply to some degree the denuded region. It is true that Henle reported a case in which three hepatic arteries were present: (*a*) from the left gastric, (*b*) the parent coeliac axis, (*c*) superior mesenteric. Rio Branco also described a triple arterial supply in another case: (*a*) a special artery from coeliac axis to the left lobe; (*b*) the usual origin and distribution from the coeliac axis; (*c*) a special branch from the superior mesenteric to the right lobe. The not infrequent derivation of the left hepatic artery from the coronary (left gastric) is vouched for by Quain, and this same indisputable authority affirms the occasional origin of the left hepatic from the superior mesenteric and its rare source from the splenic artery.

Quain also vouchsafes the information that accessory hepatic arteries are sometimes encountered, generally coming from the coronary; such a hepatico-coronary is said by Rabinovitsch (1927) to occur in no less than 28%. According to Quain, an accessory hepatic artery comes less frequently from the superior mesenteric, aorta, right renal, or inferior mesenteric; Rabinovitsch describes a hepatico-mesenteric in 18%. Thus, according to the German writer, an accessory vessel is present in nearly half the cases. Axis opinion hopefully states that since the topography of these accessory vessels is constant, their presence can easily be determined at operation (!). Tandler makes use of a less ambitious figure (32%) in relation to the frequency of an accessory artery.

In cases in which ligature of the hepatic artery is forced upon an unwilling operator gradual incomplete ligation in the manner of Halsted might be tried. There is also evidence, from animal experiment, in favour of anastomosis between the proximal segment of the ligated hepatic artery (Narath) and even of the distal segment (Ghiron) to the portal vein. Where there appears opportunity for a second intervention the omentum may also be attached to the liver at the first séance (Grunent); and an attempt may be made to produce adhesions between the liver and the diaphragm, parietes, etc. (Barch, Grunent, Bode).

There can be no manner of doubt that the anastomosis between the arterioles in the interior of the liver is infrequent and at best scanty; injection of barium in gelatin and radioscopy show that vascular communication between the two lobes is richest under Glisson's capsule and in the tissues of the portal fissure (Segall, 1923).

The anatomical findings of Continental observers and the results of experimental ligation of the hepatic arterial tree in animals other than man may afford hypnotic comfort to the surgeon confronted with the need for rapid decision, but it is an unpalatable truth that, in man, *ligature of the hepatic artery or its main branches is an operation fraught with peril to life.* The dangerous manner in which the right branch of the hepatic artery frequently clings to the cystic duct and almost defies the operator in his endeavours to separate the two "contacting" structures is familiar to every experienced surgeon. It is highly probable that many cholecystectomies performed by amateurs in which grave morbidity or death ensues owe their unfavourable course to the unfortunate inclusion of the right branch of the hepatic artery in a clamp or a mass ligature of the cystic duct and the contiguous artery.

For the accompanying sketch I am greatly indebted to my friend, Dr. C. P. Smith of Middlesex Hospital.

M. Finland and his colleagues (*Arch. intern. Med.*, 1942, **70**, 183) have observed that in patients with clinical influenza a staphylococcal pneumonia may occur and assume epidemic proportions in different places during an influenza epidemic. The authors state that the staphylococcal infection may vary from a simple tracheobronchitis to a fulminating, acute, and fatal haemorrhagic oedematous pneumonia. In such cases they recommend intensive treatment with sulphadiazine or sulphathiazole.

MEMBRANOUS INFLAMMATION OF OROPHARYNX, NOSE, AND CONJUNCTIVA DUE TO SULPHATHIAZOLE ADMINISTRATION

BY

I. M. SCHNEE

Captain, M.C. A.U.S.

Sulphonamide therapy has resulted in a variety of toxic manifestations. Many reports of the effect of the drug on various systems of the body are to be found in recent medical literature. An unusual type of toxic reaction has come under our observation. It is the appearance, following sulphathiazole therapy, of a membranous inflammation involving the conjunctiva, mucosa of the nose, pharynx, mouth, and larynx. The membrane presented the same features wherever it appeared. Rapid recovery ensued on discontinuance of the chemotherapy.

Case Report

The patient was a white man aged 28, an officer in the United States Army Tank Corps. He was admitted to the hospital on Oct. 12, 1942. On Oct. 5 he developed an infection of the upper respiratory tract. Next day he reported to his unit medical officer, who found a rise in temperature to 102°. He was put in sick quarters and sulphathiazole therapy by mouth was instituted in a dosage of 1 g. every four hours, four times daily. The same day his temperature had risen to 104°. Defervescence and relief of symptoms followed. The drug was discontinued on the eve of Oct. 10, by which time he had received a total of approximately 18 g. of sulphathiazole. On the fifth day of chemotherapy, Oct. 10, the eyes became inflamed and a discharge was present. The following day his mouth became very sore, was covered with a membrane, and the lips were cracking. On Oct. 12 there was a recurrence of fever and he was sent to hospital.

Physical examination on admission revealed a well-developed and well-nourished man, acutely ill, pale, dehydrated, dyspnoeic, and coughing. The pupils were contracted (morphine). The lids were swollen, the palpebral conjunctiva was markedly injected and covered with a smooth, thick, well-formed membrane of grey colour which left no bleeding surface when peeled off but re-formed within a few hours. The bulbar conjunctiva was injected peripherally and the membrane covered part of the outer canthus (Fig. 1). The cornea was not involved.

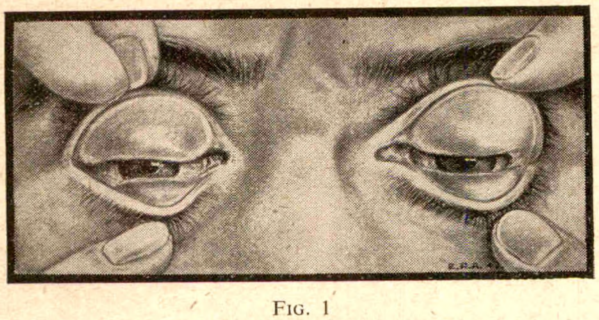

FIG. 1

Examination of the mouth revealed the same type of membrane in large patches covering the palate, fauces, floor of the mouth, gums, inside of cheeks, posterior pharynx, and larynx (indirect laryngoscopy); the nasal mucosa was involved in the same manner (Fig. 2). Ears were normal. There was no adenopathy. There was no foul odour. The mouth was very sore. Respirations were slow and not difficult. Dullness and decreased fremitus over the left lower lobe were present posteriorly. Coarse wheezing rales were heard bilaterally. The pulse was regular and of good quality. The blood pressure was 115/70. The abdomen was soft. There were no masses or tenderness, and the liver, kidney, and spleen were not palpable. Temperature was 103°, pulse 102, and respirations 26.

Smears and cultures from the lesions in the eyes, nose, and throat showed no diphtheria bacillus. The eye material revealed some staphylococci on culture, and the mouth lesions showed *Diplococcus catarrhalis.* The blood culture was negative. The blood count was: erythrocytes, 4,470,000; leucocytes, 17,000 (polymorphonuclear leucocytes 77%, lymphocytes 18%, monocytes 2%, eosinophils 2%, and basophils 1%). The urine was normal. The sputum showed no pneumococci. The Wassermann test was negative.

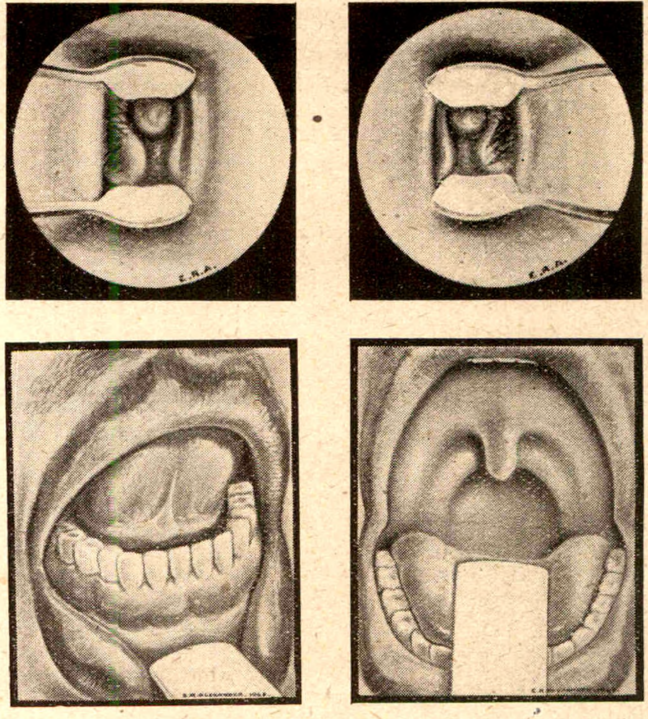

FIG. 2

Clinical Course.—Sulphathiazole therapy was resumed on admission to the hospital in a dosage of 1 g. every four hours. The eyes were treated with sublimate 1 in 10,000 solution, irrigation and instillations of sulphacetamide 2.5% solution, and oily drops. The nose, mouth, and throat were irrigated with antiseptic solutions. The temperature was declining and the general condition was improving, but the eyes and oropharyngeal and nasal lesions were getting worse in spite of treatment. The membrane became more extensive and confluent. On Oct. 14 it was decided by Lt.-Col. Derrick T. Vail, M.C. A.U.S., Senior Consulting Ophthalmologist, that these unusual clinical features might be due to the chemotherapy, and accordingly the drug was ordered to be discontinued. The following day there was marked subjective improvement in the discomfort of the eyes and mouth, but no improvement objectively, though the lesions were not worse. On Oct. 17 the patient showed definite signs of improvement; the lesions began to clear rapidly and the membrane was sloughing in patches. On Oct. 19 the eye membrane was completely cleared up and there was only slight conjunctival injection. On Oct. 21 the eyes had completely recovered, but the mucosal lesions were still present in small patches here and there. The temperature had remained normal since Oct. 18 and the general condition was good. On Oct. 24 all the mucosa appeared healthy and the eyes were perfectly normal.

Appreciation is expressed to Brigadier Sir W. Stewart Duke-Elder, A.M.S., Major Lister, R.A.M.C., and the artist for their courtesies.

CORONERS' DISTRICTS IN LONDON

The Public Control Committee of the London County Council is proposing to reconstitute coroners' districts in London, making four districts instead of five as at present. The number of inquests has decreased owing to the war conditions, especially evacuation, and it is considered that the work can now be adequately carried out by four coroners. The approaching retirement of a coroner gives a suitable opportunity for making the change. The proposed new districts will be northern, southern, eastern, and western; previously, instead of a southern district, there had been south-eastern and south-western. The four coroners to whom the districts will be assigned are, respectively, Mr. Bentley Purchase, Mr. Hervey Watt, Mr. W. R. H. Heddy, and Mr. Neville Stafford. The measure is a wartime one and will be reviewed after the war.

THE EFFECT OF ACID, ALKALI, AND MEALS ON THE BLOOD LEVEL AND EXCRETION OF SULPHAPYRIDINE IN CHILDREN

BY

H. ELLIS C. WILSON, M.B., D.Sc., F.R.F.P.S.

Biochemist to the Royal Hospital for Sick Children, Glasgow

The effect of the sulphonamide drugs on the acid-base metabolism has received a certain amount of attention without, however, any clear-cut conception as to the nature or cause of the upset having been obtained. Beckmann *et al.* (1940) have shown in adults that with doses of about 6 g. a day there is a proportionate fall in the sodium and bicarbonate, with a rise in the chloride of the blood. These changes were associated with a temporary increase in the sodium excretion and a smaller one in the chloride excretion which shortly fell to the normal rate of output. They state that the electrolytic pattern of the blood resembles that observed after the administration of acid salts such as ammonium chloride and ammonium sulphate, except that the increase in the blood chloride is bound to sodium in the case of the acid salts, while after sulphanilamide they assume that the extra chloride must presumably be bound to the serum proteins.

These authors hold that the primary effect of the drug is to cause an increased excretion of sodium bicarbonate, which produces secondarily a certain degree of hyperpnoea (i.e., an acidosis). Hartmann *et al.* (1938) also observed a hyperpnoea and a fall in blood CO_2. They, on the other hand, consider the hyperpnoea to be the primary change which accounts for the excretion of bicarbonate to keep the *p*H of the blood normal (i.e., an alkalosis). Beckmann *et al.* (1940) maintain that this latter explanation is unlikely, as it would require a greater degree of hyperpnoea to cause the reduction in blood bicarbonate observed.

Whatever the explanation, the net result appears to be a reduction in the fixed base of the blood, and hence an acidosis. It is perhaps this belief which has led to the giving of alkali along with the drug in order to relieve acidosis. The possibility of increased excretion and absorption, and the alleviation of undesirable symptoms such as vomiting, also require consideration. The scope of the present investigation was as follows: (*a*) to test the effect of acid and alkali on the blood level and excretion of sulphapyridine in children; (*b*) to test the effect of the timing of meals on the blood level and excretion of sulphapyridine in children.

Effect of Acid and Alkali

The subjects chosen for investigation were between 4 and 12 years of age and had been admitted to hospital with diseases unlikely to interfere with the absorption and excretion of the drug—e.g., chorea and epilepsy. In a series of 15 cases each child was given a single dose of 50 mg. of sulphapyridine per kilo of body weight, and the blood level followed at one-, four-, and eight-hour intervals. The excretion in the urine for the first 24 hours was also estimated. Three separate tests were carried out on each case: (1) sulphapyridine alone; (2) sulphapyridine and 30 gr. of sodium bicarbonate; (3) sulphapyridine and 19 gr. of ammonium chloride (the acid equivalent of 30 gr. of sodium bicarbonate). The estimations were made according to the method of Bratton and Marshall (1939). Both total and free sulphapyridine estimations were made on the urine, but in the blood the free form only.

The average results obtained are given in Table I, A. The individual figures vary considerably, but the averages did not show that there was any advantage in giving or withholding either acid or alkali. The excretion of the drug (50% in 24 hours) was the same in the three modes of administration (Table I, B). On an average about 50% of the amount excreted was in the free form, leaving the remainder as a combined form, probably the acetyl derivative. The amount of the combined form varied between 17 and 68% in the different cases. The only relatively constant feature was the percentage amount of the combined form in each individual case in the three modes of administration, even although the total excretion varied. As all the children had essentially the same diet it is unlikely that food was a factor in the detoxicating process. Further, there appeared to be no correlation between vomiting and the giving of acid or alkali. Several of the cases vomited at varying intervals after getting the drug. Such observations were discarded, the investigations being repeated a few days later. Had the diminution of fixed base of the blood been a contributory cause of vomiting one would have expected that the giving of alkali or acid would have respectively improved or aggravated the condition. Such was not found to be the case. In one particular child, who vomited within half an hour of receiving the drug, the blood level was above the average an hour later. The extreme variability of the blood curves and percentage excretion both from case to case and in the same individual has been noted by others for sulphapyridine (Brown, Thornton, and Wilson, 1939; Cullen and Wilson, 1940). Barlow and Climenko (1941), however, claim that with sulphapyridine the giving of alkalis such as sodium bicarbonate and magnesium carbonate increased the excretion of sulphapyridine. Their figures are, however, in our opinion and considering the variability, too few and probably not significant. Siebert and Loose (1940) observed no difference in the absorption of sulphanilamide when given with 30 gr. of sodium bicarbonate. They found, further, that gastric acidity did not appear to influence absorption, and in support of their claim instanced a case of achlorhydria in which the excretion was normal.

TABLE I

A.—Average Concentration of Free Sulphapyridine in Blood at 1, 4, and 8 Hours (15 Cases)

	1 Hour (mg./100 c.cm.)	4 Hours (mg./100 c.cm.)	8 Hours (mg./100 c.cm.)
Sulphapyridine alone	4·5	5·1	4·8
Sulphapyridine + 30 gr. $NaHCO_3$	3·8	5·4	4·5
Sulphapyridine + 19 gr. NH_4Cl	3·8	5·5	4·6

B.—Average Output of Drug in Urine (15 Cases)

	Drug excreted in 24 Hours	Form of Drug	
		Free	Combined
	%	%	%
Sulphapyridine alone	49·05	53·8	46·2
Sulphapyridine + 30 gr. $NaHCO_3$	51·0	54·4	45·6
Sulphapyridine + 19 gr. NH_4Cl .. .	50·6	50·4	49·6

Effect of Meals

The second series of cases (Table II, A) was designed to test the effect of taking the drug two hours before and immediately after the midday meal. In all, 17 children were studied. One blood sample was taken four hours after administration and the urine was collected for 24 hours. The figures again were extremely variable. The average blood level was 0.5 mg. higher when the drug was taken after the meal.

TABLE II

A

	Mg./100 c.cm.	Standard Deviation
Average blood sulphapyridine 4 hours after dose taken between meals	5·3	d=1·54
Average blood sulphapyridine 4 hours after dose taken immediately after meal	5·8	d=1·73
Difference ..	0·5	

B

Average excretion of sulphapyridine in 24 hours drug taken between meals	60·7%	d=15·4
Average excretion of sulphapyridine in 24 hours urine. drug taken immediately after meal ..	66·2%	d=13·5
Difference ...	5·5%	

The standard deviations were 1.54 and 1.73, and the probable error of the difference of the means was 0.2716. The ratio of the difference of the means is hence 0.2716:0.5=1.8. When this is less than 3 it is usually considered not to be significant. When the drug was administered immediately after a meal the percentage excretion in urine was 5.5 greater than when taken between meals. The standard deviations were 15.4 and 13.5 respectively. The above-mentioned ratio in this case is 6.5, and hence the difference can be considered to be statistically significant, although from the clinical point of view it is scarcely of importance.

Conclusions

The data presented here would appear to show that there is no advantage with respect to the blood concentration or urinary excretion, and hence absorption, in giving acid or alkali with sulphapyridine. Nor was any significant effect observed on the blood concentration by timing the administration of the drug in relation to meals. The excretion of the drug was greater when taken immediately after as opposed to two hours before a meal. This difference was statistically significant, but clinically can scarcely be of much importance.

I desire to thank Dr. Stanley G. Graham for his advice and criticism in the preparation of this paper.

Medical Memoranda

Encephalitis after Measles with Severe Parkinsonian Rigidity: Recovery

Although variability in the signs and symptoms produced by encephalitis is notorious, the following case which followed upon an attack of measles is of interest on account of the predominance of the Parkinsonian syndrome from the onset.

CASE HISTORY

The patient, a boy aged 6, was admitted on Sept 10, 1942, with a history that nine days previously he had developed a typical mild attack of measles. This was treated at home by his medical practitioner, who confirms that the illness had every appearance of ordinary measles. Seven days later the doctor was called in again on account of some stiffness in the limbs and the fact that for the last day or two the boy failed to answer when spoken to When he was brought to the hospital two days later he had during the interval uttered only one or two short spontaneous remarks, and, as he did not speak and had a strange expressionless face, the mother thought he was suffering from some kind of mental derangement.

On examination the patient showed a typical Parkinsonian facies, emotional as well as voluntary facial movements being absent The tongue could not be protruded, and there was some dribbling of saliva from the corners of the mouth. Crying resulted in a peculiar whining noise. There was some difficulty in swallowing, but fluids could be taken fairly well Drowsiness was not apparent. The eyes were unaffected, and when asked to follow a moving object he responded promptly. All limbs showed well-marked Parkinsonian rigidity and tremor, and were affected almost equally; but with a little assistance he was able to get off the couch and walk round the room. At this stage tendon jerks were brisk, plantar reflexes normal, and the lower abdominal reflexes absent. The fundi were normal, and remained so throughout the illness. There was no nystagmus or strabismus, and the pupils reacted normally. During the illness the C.S.F. was normal on two occasions in respect of sugar, chlorides, and leucocytes, but contained a few red cells (probably contaminants) and a total protein of 0.06% and 0 05%. The blood W.R. was negative and the blood count normal. During the first two weeks the temperature was 100° F. on a few occasions, but was later normal.

During the first ten days in hospital the condition became progressively worse. The arms, particularly the right arm, became fixed in a position of flexion, tremor was very pronounced, and the knees tended to become flexed. Voluntary movements had practically disappeared. For a short period a transient left internal strabismus occurred, and the left plantar response became extensor. There were also at this stage frequent attacks of restlessness with increased tremor and flexion of the arms and knees. There was no inversion of sleep rhythm. Sphincters were unaffected, and he continued to be able to swallow. On the eighteenth day of the illness the patient spoke a few words, and within a week posture was almost normal. At about this time he was emotionally labile and his speech rather confused. He was discharged from hospital, apparently completely normal, on Oct. 12, 42 days after the onset of the measles rash.

Treatment consisted of general measures and the administration of large doses of pot. brom. and tinct. hyoscyami, and frequently chloral at night. Somewhat empirically, three injections of liver extract were also given intramuscularly.

Since leaving hospital the boy has been in good health, and attends school, where he also plays games. In a recent examination no abnormality could be found in his central nervous system. The fundi were normal; there was no strabismus or tremor. Vision was 6/6 and hearing normal. No character change has been noted by his mother, and at school he is well up to the average. There is no relevant family history.

It appears that in spite of the prominence of Parkinsonism a diagnosis of post-measles encephalitis rather than of a lethargic type of the disease should be made in this case. This is supported by the history of measles and by the completeness and rapidity of recovery.

I wish to thank Dr. W. E. Crosbie, medical superintendent of the hospital, for permission to publish this case; and Dr. Norman B. Capon, visiting consultant physician, for his advice and supervision.

Alder Hey Hospital, Liverpool. B. MEYER, M.B., B.S., D.C.H.

A Case of Malignant Tertian Malaria

Malignant malaria is seldom seen in this country, though Murray and Shute (1942) have recently reported a case. The following case is remarkable for its benign clinical course and for the manner in which it responded to small doses of quinine.

CASE RECORD

The patient, a ship's steward, was admitted to the General Hospital, South Shields, on Aug. 27, 1942, with a history of "malaria." He had been torpedoed off the West African coast in March, 1942, and after two days at sea was interned in French West Africa. He was kept in insanitary conditions, on a poor diet, until his release at the end of June. During this period he is said to have contracted "malaria" and "dysentery." During July and August he had regular attacks with rigors at intervals of 3 to 4 days. The last rigor occurred the night before admission. He had had no systematic treatment, but had taken "a few quinine tablets now and then."

On admission to hospital he was noted to be thin and pale, but not emaciated. Clinical examination was negative apart from some tenderness in the left epigastrium. The liver and spleen were not palpable, the conjunctivae were pale, there was no jaundice, and urine analysis proved negative. Temperature on admission was 99.4° and pulse 104. Next morning the temperature was subnormal; it rose again in the evening, to 100°, and returned to normal the following morning. There has been no subsequent rise in temperature.

Blood films taken on Aug. 29 showed large numbers of malaria parasites, chiefly the gametocyte stage of *P. falciparum*, together with some ring forms. Although the films were only ordinary thin ones, parasites were so numerous that some fields showed two crescent forms. A further film on Sept. 8 contained crescent forms in fair numbers. On Sept. 23 only a single ring form was seen. Subsequent films have been negative.

Treatment.—The patient was put on quinine sulphate gr. 5 t.d.s. on admission, before the blood had been examined. This was discontinued on Sept. 2. On Sept 6 he had one dose of 10 gr., and on Sept 8 quinine sulphate gr. 5 t.d.s. was reinstituted. On Oct 3 the patient was discharged apparently well, having then been apyrexial for 36 days. He was gaining weight and the signs of anaemia noted on admission had largely disappeared, although he had had no specific treatment to combat the anaemia. At the end of October he was still taking 5 gr. of quinine thrice daily, and, while that was too soon to speak of cure, there had been no recurrence of symptoms and films remained negative

It should be mentioned that the patient gives a history of having contracted malaria ten years ago and having had subsequent attacks at intervals of a few months up to the onset of the present illness. It is most improbable that he has been suffering from malignant malaria for ten years, particularly in the absence of splenic enlargement. That he contracted any form of malaria ten years ago is doubtful: there is no medical confirmation, and seafaring men commonly refer to any pyrexial illness as "malaria."

The presenting symptoms in Murray and Shute's case were gastro-intestinal, and it is interesting to note that diarrhoea ("dysentery") had been an early symptom in our case, but had subsided before admission. Manson-Bahr (1942) states that malaria is often accompanied by diarrhoea, and mentions "malarial dysentery" with blood and mucus in the stools.

Our thanks are due to Dr. D. J Mackinnon (late R A M.C., East Africa), who confirmed the diagnosis, and to Dr. W. Campbell Lyons, medical officer of health, South Shields, for permission to publish this note.

Reviews

SURGICAL DISEASES OF THE SPINAL CORD

Surgical Diseases of the Spinal Cord, Membranes, and Nerve Roots: Symptoms, Diagnosis and Treatment. By Charles A. Elsberg, M.D. (Pp. 598; illustrated. £4.) London: H. K. Lewis and Co. 1942.

Fifty years ago it must have been hard to accept the novel idea that diseases of the spinal cord might be amenable to surgery; at the present time every student knows the importance of seeking for evidence of spinal compression whenever there is progressive interference with the function of the cord, and this changed attitude is attributable to the pioneer work of a comparatively small group of neurosurgeons, among whom Prof. Elsberg may rightly claim a place of honour. The many workers in this field, and also outside it, who valued his earlier works—*Diseases of the Spinal Cord* and *Tumours of the Spinal Cord*—will welcome his new book entitled *Surgical Diseases of the Spinal Cord, Membranes, and Nerve Roots.*

Notable features in the early chapters on anatomy and physiology are the descriptions of the lamellar arrangement of the spino-thalamic tract, which make clear certain puzzling clinical signs; and of the skin and muscle distribution of the spinal nerve roots, which differ in many respects from earlier accounts. The part on examination of the cerebrospinal fluid, with special reference to the establishment of subarachnoid block, is well done. There are chapters of outstanding merit on *x*-ray diagnosis by Dr. Cornelius G. Dyke, and on the pathology of tumours of the spinal cord by Dr. Abner Wolf. Though the introduction of contrast media receives due attention, the most impressive feature of Dr. Dyke's contribution is the astonishing amount of information that may be obtained from plain *x*-ray films which are properly taken and carefully interpreted.

The book gives a full and authoritative account of the symptomatology and treatment of all varieties of spinal cord tumour, and considering how thoroughly this field is covered it must be admitted that injuries and infections of the cord and its coverings are comparatively lightly touched upon. One further criticism of an otherwise excellent work of reference must be that the bibliography does less than justice to many of the English neurologists and neurosurgeons who have contributed to the advance of this subject in recent years.

DISSECTION OF A CITY

The Population of Bristol. By H. A. Shannon and E. Grebenik. National Institute of Economic and Social Research: Occasional Papers, II. (Pp. 92. 7s. 6d.) Cambridge: The University Press. 1943.

The changing population of Bristol as affected by inward industrial migration and by fertility rates has been exhaustively studied by two statisticians. The study is based on pre-war material, and as Bristol has suffered immense dislocation as a result of the war a further study seems to be called for as soon as post-war trends can be discerned. Mr. Shannon deals with the respective numbers of Bristolians and migrants (chiefly from Wales and South-West England), and their respective chances of absorption into employment. Mr. Grebenik is concerned with the fertility of the Bristol population. The medical officer of health has a record over a period of years of the age of the mother of every daughter born, and from this it has been possible to estimate net reproduction rates. The population of Bristol in 1937 was 415,000. On the assumption that fertility and mortality remain at the same level as in that year, and that there is no net inward migration, the population will begin to decrease after 1949, and by the year 2000 will be only 273,000. One point brought out in the survey—not an unexpected one—is that the first, second, and third confinements of the wives of unskilled labourers all take place at a distinctly lower age than among women of the higher economic and occupational groups. The mean age at the birth of the first child to wives of unskilled manual workers is 24.56 years, as compared with 27.95 for the professional, business, and commercial classes, including clerks. The parity pattern for labourers' wives is also different from that of the other groups. Their mean parity for all ages is 3.55, whereas the corresponding figure for the professional and commercial class is 1.83, for minor commercial people such as shopkeepers 2.02, for supervisory and skilled manual workers 2.07, and for the semi-skilled 2.37. The researches have been made possible by generous grants from the National Institute of Economic and Social Research supplemented by the Colston Research Society and anonymous donors.

ANIMAL PARASITES

Introduction to Parasitology. By A. S. Pearse, Professor of Zoology, Duke University. (Pp. 357; illustrated. $3.75 or 21s.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1942.

This book, being a general survey of animal parasites—not parasites of animals—is primarily intended for students of zoology who may be required, or wish, to have some knowledge of the structure and life histories of those representatives of the various animal groups which have developed a parasitic mode of life. It opens with an introduction in which nomenclature, oecology, and adaptation are briefly considered, and then passes on to descriptions of the various parasites themselves, beginning with the protozoa and finishing with certain parasitic vertebrata. Special attention is given to parasites of economic importance, emphasis being laid on those apt to infect or injure man or domestic animals. The volume is profusely illustrated with clear outline drawings, while many life-cycle diagrams help to clarify the descriptions and statements made in the text.

It is pointed out that one of the most important essentials in the prevention of infections is widespread knowledge of the life histories of the parasites and a comprehension by the public of the manner in which such infections are brought about. Certainly the book goes a long way towards simplifying the acquirement of this necessary knowledge, and it can be thoroughly recommended as a reliable guide to students of parasitology.

Notes on Books

A seventh edition of the well-known book *Surgical Ward Work and Nursing*, by Mr. ALEXANDER MILES and Miss G. F. NUTTALL, is an indication of its deserved popularity. Revision for this edition, however, has not in our opinion been radical enough. Several illustrations might with advantage have been discarded—e.g., Cheselden's, Chiene's, and Buchanan's lithotomy staffs, MacIntyre's, Liston's, Heron Watson's, and Dupuytren's splints, Shaw's skull flaps, and Moynihan's intestinal evacuation tube. These, among others, are of only historical interest, and the already overworked student nurse need not be further burdened by memorizing now useless pieces of apparatus. Figure 73, claimed to be a Staffordshire knot, is really a half-hitch. The anaesthetic apparatuses illustrated appear to be rather primitive, and more modern types might profitably be shown in the next edition, in which also some mention of chemotherapy and the sulphonamides might be made. Nutrient enemas, of doubtful value, are mentioned, but there is no word of the magnesium sulphate retention enema; and Reverdin's needle and Michel clips are referred to as a handled needle and suture clips respectively, instead of by their more widely known names. The publishers are Faber and Faber, and the price is 12s. 6d.

Preparations and Appliances

HYPOLOID METHEDRINE

"Hypoloid methedrine" (*d*-N-methylamphetamine hydrochloride), prepared by Burroughs Wellcome & Co., is a sympathomimetic pressor agent with a prolonged action. It is intended primarily for administration before or during operation to maintain the blood pressure and guard against shock, particularly when spinal anaesthesia is used; it is claimed that a single injection suffices in the majority of cases. The drug is also stated to be of value as an analeptic in collapse or poisoning from overdosage of anaesthetics or narcotics or exposure to noxious gases. Hypoloid methedrine is issued for intravenous, intramuscular, or subcutaneous injection in ampoules containing 30 mg. in 1.5 c.cm.

AN ANTACID

Although the newer antacids such as magnesium trisilicate and aluminium hydroxide are safer and more effective in the treatment of peptic ulcer than the simple alkalis they do not give the same immediate relief to the patient. Westminster Laboratories have therefore endeavoured to get the best out of both worlds by introducing "Magtriz," which is a mixture of 91% magnesium trisilicate and 9% magnesium hydroxide. It may be obtained as a powder or as a liquid flavoured with peppermint, and should be a useful adjunct to the treatment of peptic ulcer.

THE CONSTITUTIONAL FACTOR

Though it is often alleged that the medical profession are slow to adopt new ideas, it is certainly true that they allow a new idea, once adopted, to deflect the stream of medical thought too violently. Of this, bacteria, hormones, and deficiency diseases are outstanding examples. Each in turn diverted attention from the constitutional factor in disease. The old conception of diathesis was not modernized but rather ignored. True, round about the turn of the century Bland-Sutton[1] on the structural side, and Archibald Garrod[2] on the biochemical, did something to stem the tide, but it is to the professed geneticists that we are indebted for the accumulation of data which are now reinstating the constitutional factor in our conception of disease. To that change Prof. Julius Bauer's important book *Constitution and Disease*[3] bears testimony. To some, indeed, it may appear that he overstresses his line of thought, much as his predecessors had done theirs. Nevertheless he adduces valuable evidence. Passing from Vienna to Los Angeles, he attributes the neglect of the constitutional factor in the United States to the absence of that traditional background which in Europe had preserved some interest in it. He does justice, however, to Dr. George Draper's elaborate studies in New York on *Human Constitution*,[4] though often differing from his conclusions.

Poincaré said that a mere piling up of facts is as little a science as a heaping up of stones is a house. Bauer's emphasis is on the house rather than the individual stones. He reminds us that a "normal" man is a mental abstraction. Only 9% of people have a greater splanchnic nerve which corresponds to the textbook description, and reasons are given for assuming that only if a variation occurs in less than 4.5% of the population should it be considered an abnormality. This wide variability follows inevitably from the infinite alteration possible in the pattern of the genes produced by mating. "Heredity determines what one can do, environment determines what one does do." Some structural abnormalities may not endanger health unless unusual physiological conditions arise, but others may have more far-reaching effects. This is the group originally called abiotrophies by Gowers, and more recently studied by Parkes Weber, the members of which are characterized by biological inferiority of certain organs, leading them to wear out prematurely under the strains of normal functioning. It is a mistake to attribute this to focal infections, vitamin deficiencies, or endocrine disturbances. A generalized abiotrophy due to "a mess in the chromosomes" leads to "status degenerativus" and precipitates senescence. Short of this, a defective gene may lead to several abnormalities through "pleiotropism," as seen in fragilitas ossium, blue sclerae, and otosclerosis in varying combinations and degrees in different members of a family. Moreover abiotrophy may be unilateral. Disease varies directly with the severity of the lesion and inversely with the individual's power of resistance. Thus amidopyrine may lead to agranulocytosis, but only in those with an easily exhausted bone marrow. It is unnecessary to discuss such a well-known instance of genetic disease as haemophilia, but it is of interest to mention the combination of hereditary mental deficiency with the excretion of phenylpyruvic acid in the urine, both because R. A. Peters has shown that pyruvic acid, an intermediate product in the metabolism of carbohydrate, can be detected in nerve cells, and requires vitamin B_1 for its disposal, and because the vitamin B complex has been found useful in various psychoses.[5] Thus it appears probable that biochemistry can come to the aid of a genetic defect.

Bauer's main conception is that the genes act directly on the effector organ, or indirectly through either the endocrine system or the nervous system, which can themselves collaborate. He thinks too much stress has been laid upon the endocrine system as an initiator rather than as the mediator between constitution and the effector organ. Like H. H. Dale, he emphasizes the importance of the receptivity of the organ to hormonal stimulus, which explains cases where the endocrine lack is expressed in only one organ. Here the organ must have an unduly high threshold for endocrine stimulation, rather than a fault in the hormone itself. Not all cases of infantilism are genetic or hormonal in origin; as is well known, it may result from chronic disease acquired early in life. The testing time for the biological worth of an endocrine system may come later in life—e.g., at the menopause or during pregnancy. Thus some pregnant women develop tetany, and others acromegalic features; both alterations disappearing on delivery, though some may show signs of temporary pituitary exhaustion afterwards. Biological inferiority need not connote intellectual or artistic inferiority. Indeed, Beethoven's otosclerosis, Mozart's early tuberculosis, and Darwin's psychoneurosis may be regarded as examples of the way in which genius has to pay for its cultural superiority by biological inferiority.

It may be thought that this attitude towards disease spells pessimistic nihilism; but, although genetic factors represent the unchangeable fate of a person, we are nevertheless able to do a great deal for those whose inherited tendencies may be complicated by unfavourable conditions. That medicine is passing from healing to prevention is a dictum which is repeated with almost tiresome reiteration; tiresome because, apart from the work of the medical officer of health, views as to individual prevention remain vague. Here is a field in which it can be applied by regulation of diet, habits, and mode of life, and by advice as to occupation so as to diminish the strain on the faulty structure. Nor, as Bauer says, is the psychotherapeutic aspect to be neglected, for all medicine must be psychosomatic. The routine performance of needless tests has a harmful influence, and unless the young practitioner learns what may be safely disregarded he can become a fertile breeder of neuroses. "Watch your word" is a maxim never to be forgotten by the physician. His word is a therapeutic instrument no less powerful and no less dangerous than the surgeon's scalpel.

CUTTING THE FRONTAL WHITE FIBRES

Recent work on the function of the frontal lobes in man has made it hardly frivolous to ask: Is a frontal cortex really necessary? In a leading article[6] in this *Journal* two and a half years ago the evidence was summarized for supposing that when a large part of the frontal lobe has been destroyed mental functions can still be carried on at a high level. At the last quarterly meeting of the Royal

Medico-Psychological Association, when a symposium on prefrontal leucotomy was held, Prof. Golla illustrated from both animal experiments and operations on man how nearly perfectly all functions temporarily lost by ablation of the prefrontal areas can be taken over by other parts of the brain. So far as man is concerned the evidence on these matters has hitherto come from the after-results of surgical operation on the brain such as the removal of tumours or scar tissue; the operation of leucotomy for the alleviation of mental disease is now providing further evidence. This operation, introduced by Prof. Edgar Moniz[7] of Lisbon in 1936, aims at cutting the white matter of the frontal lobes in such a way as to divide the frontal thalamic association fibres. The basis for this enterprise has been a clinical observation that after a frontal-lobe injury the individual may develop a mild euphoria, a condition preferable in many ways to the chronic unalterable depression for the treatment of which the method was introduced. Early results of the operation demonstrated, in addition to this tendency towards euphoria, a lessening of emotional tension, with freedom from anxiety and worry and a diminution of distractibility and mental fatigue. After the favourable results obtained in depressive and obsessional states the scope of the operation has been widened to include other disorders in which the predominant symptoms are severe emotional tension, psychic overactivity, destructiveness, and violence. Palmer[8] has reported remarkable symptomatic amelioration in long-standing, overactive schizophrenics, and similar improvement in behaviour has been observed in some gravely antisocial epileptics and in psychopathic personality states. Freeman and Watts,[9] the American pioneers in this field, have lately completed a comprehensive treatise on the subject; a more concise review is provided by McGregor and Crumbie.[10]

Accounts of the experiences of nearly all the main centres at which leucotomy has been practised in this country were put before the R.M.P.A. at its meeting on March 10. There was general agreement among speakers that the operation does not specifically cure any particular form of mental disease, but tends to relieve certain groups of symptoms, particularly emotional tension, agitation, and apprehension—typically seen in agitated depressions—and overactivity, destructiveness, and impulsive violence characteristic of many cases of catatonic schizophrenia. Duration of symptoms appears to be of far less prognostic importance than it is in convulsion therapy; a number of patients whose symptoms had persisted for over ten years were reported as being greatly improved. Although in many of the cases described the mental disorder was so advanced and the prognosis so poor as to justify the greatest risks, the dangers of the operation, particularly in the treatment of earlier cases, should not be lightly disregarded. Many will endorse the opinion expressed by Mr. Wylie McKissock that the operation requires the best operative facilities and an experienced neurosurgeon. In some 200 cases reported at this meeting the mortality rate was less than 5%. Disturbance of the higher intellectual factors is not easy to ascertain, but increasing knowledge tends to be reassuring. It is noteworthy that artistic and creative capacities may be recovered as well as a capacity to plan for future action. This is not to say that restoration of function is complete; there is apt to be some weakness of inhibition, giving an impression of childishness, mild euphoria, and a lack of depth of emotion and responsiveness. But some observers have failed to detect any intellectual deterioration. In some cases, no doubt, the mental capacity and standard of behaviour of the person before the onset of the psychosis were not accurately known. A silk purse cannot be made out of a sow's ear—even by prefrontal leucotomy. Hutton[11] has remarked that the patients seem to live on a superficial level of contemporary associations and to be unable to make much use of past experiences. It is possible that lack of uniformity in the amount of brain damage, differences in the constitution of individual brains, or variations in the extent and depth of original disease process account for these discrepancies in the findings of various observers. But the striking change after an operation, the relatively slight intellectual impairment, the restoration to a large extent of the inhibitory functions of the central nervous system—a wildly disturbed schizophrenic becomes entirely amenable—raises a number of puzzling questions as to the nature of mental disease and the function of the frontal lobes. Is it to be supposed that mental disease may depend on some disorder of the communication between the forebrain and the thalamus, so that excitation arising at the base of the brain cannot be properly inhibited so long as the frontal thalamic tracts are intact? Or is it to be supposed that a persistent disturbance in either the frontal or thalamic region sets up a vicious circle of excitation?

Further knowledge will narrow the range of speculation. Leucotomy is still in the experimental stage. Nevertheless it has already brought relief to many of the unhappiest of disordered minds; it is, incidentally, adding to our knowledge of the functions of the brain in health and in disease.

APPENDICAL MECHANICS AND APPENDICITIS

A notable contribution to the study of appendicitis and its causation in man is made by C. Dennis[12] from the University of Minneapolis, who has investigated both the physiological behaviour of the human appendix and its reactions in states of inflammation. He suggests that in certain cases appendicitis results from obstruction in the appendix of a muscular or functional nature rather than from an organic occlusion, and that in other cases previous mild inflammation may cause secondary organic obstruction with attacks of increasing severity as the degree of organic obstruction increases. The obstructive origin of appendicitis is generally accepted, but a large number of cases occur in which organic obstruction cannot be satisfactorily demonstrated. It can be shown radiographically that the normal appendix actively fills and empties. In a large series of observations Dennis confirms the activity of this organ, and notes the different types of muscular movement of which it is capable. In the living subject, studied after a special appendicostomy procedure, he records three types of waves: the rapid pendular contractions, occurring every 7 to 10 seconds; small tonus waves, occurring about every 60 seconds; and large tonus waves, coming every 10 to 20 minutes.

Inflamed appendices showed varying degrees of inhibition of these movements, and different reactions to different drugs. Morphine depressed activity, as did adrenaline and ephedrine, while acetylcholine and physostigmine increased it, the reactions on the whole being similar to those already known for the ileum. In a series of experiments designed to estimate the intra-appendicular pressures in man, Dennis showed that with obstruction this pressure rises to approximately 100 cm. of water, due to the secretion of fluid by the mucosa; the normal rate of secretion is only about 3 c.cm. per day. Such obstruction, leading to tension on the muscular wall of the appendix, is regarded as the cause of the pain of appendicitis, including both the general abdominal pain and that radiating to the right lower quadrant. Obstruction to outflow from the appendix is thought by Dennis to be due in some cases to simple muscular spasm, the cause of which, however, is uncertain. In such spastic obstruction fluid is likely to escape from the appendix at not too high a pressure, so that the mucosal injury produced by a sustained moderate pressure may lead to inhibition of further secretion after a time, and so the process will gradually subside. Dennis gives evidence that the average resistance to outflow of fluid to the caecum through the inflamed appendix was three times that of the normal, such resistance being mainly due to increased tonus of the circular muscle.

[12] *Arch. Surg.*, 1941, 43, 1021.

These arguments are strongly against the view that appendicitis is mainly due to stasis secondary to lack of active movements, though complete obstruction with active mucosal secretion inevitably leads to secondary stasis and gangrene. Above a pressure of about 90 cm. of water, seepage through the appendicular wall is likely to occur, thus explaining the many cases of peritonitis without rupture. On the other hand an intraluminal tension of over 2 atmospheres is possible without bursting the normal appendix wall, though, when it is inflamed, rupture may occur through digestion of the wall.

CONTROL OF DRUGS OF ADDICTION

The League of Nations, through its Advisory Committee on Traffic in Opium and Other Dangerous Drugs and its Permanent Central Opium Board, continues, though suffering from many impediments, to exercise international control of the commerce in narcotics. The need for vigilance and the danger of any relaxation were emphasized by the experience gathered in the last world war. The usual statistical returns, due from contracting Governments under some of the international opium conventions of 1912 to 1931, are lacking in some cases, and annual reports for the year 1939 have not been received from Germany, Denmark, France, Spain, Italy, Norway, Netherlands, Poland, Portugal, Czechoslovakia, Russia, Yugoslavia in Europe; nor from Afghanistan, Sa'udi Arabia, Japan, and some South American countries. Accessions to some of the international conventions have, however, been secured in the case of Egypt, the Belgian Congo, and Paraguay. China is pursuing her six-year plan for suppression of poppy cultivation, opium smoking, and drug addiction, while in the territories overrun by Japan the abuse of narcotics is becoming increasingly serious.

As regards drug addiction, it was reported that in the United Kingdom and Northern Ireland the number of addicts known to the Central Office in 1939 was 534, of whom 269 were men and 265 women; 121 were members of the medical profession, 3 were dentists, 5 pharmacists, and 2 veterinary surgeons. The drug employed was morphine in 78.7% of the cases and heroin in 13.2%. Much attention has been directed in the United States to the nation-wide marihuana problem and the cultivation and importation of Indian hemp, from which the marihuana is derived. During 1939, 951 violations of the Marihuana Tax Act were reported; 1,545 seizures of the drug in various forms were effected and 864 arrests. A campaign throughout the U.S.A. for the eradication of the Indian hemp plant was carried out in 1939, involving approximately 9,026 metric tons of marihuana growing on 4,542 hectares of land, while it was estimated that the total area of uneradicated marihuana growth in the United States is approximately 18,211 hectares. In Turkey the area under poppy cultivation in 1939 had increased to 31,129 hectares and the raw opium produced amounted to 262,309 kilogrammes. In British India the cultivation of the opium poppy is now confined to the United Provinces, where 2,657 hectares were under cultivation in 1939, the whole opium produce being sold to the Government factory at Ghazipur. The quantity of opium produced in the year amounted to 39,796 kilogrammes, with a morphine content of 11%. The amount of morphine manufactured in the United Kingdom in 1939 was rather more than in the previous five years and amounted to 3,628 kilos, that of heroin to 190 kilos. In the same year 407 kilos of British morphine were exported to other countries and 740 kilos of codeine.

The Permanent Central Opium Board, of which Sir Atul Chatterjee is president, emphasizes the importance of continuing the work it has performed for the last twenty years, and is satisfied to know that this view is shared by the great majority of the contracting Governments.

COMPULSORY PASTEURIZATION OF MILK

The People's League of Health has conducted for the past thirteen years a "safe milk" campaign throughout the country and has now drawn up a further memorandum on the subject, dealing in particular with the compulsory pasteurization (treatment of milk in accordance with the Regulations prescribed by the Ministry of Health) of all milk for human consumption except that derived from tuberculin-tested, tubercle-free herds. Modern methods of collection and distribution of the milk supply in bulk result in milk from one cow suffering from tuberculosis infecting other milk, possibly of a very high standard and free from such infection. The memorandum is signed by Sir William Savage, chairman of the Safe Milk Committee of the League, and is endorsed by influential supporters, including Sir Henry Dale, P.R.S., Lord Moran of Manton, P.R.C.P., Sir Alfred Webb-Johnson, P.R.C.S., Viscount Dawson of Penn, Lord Horder, Dr. C. O. Hawthorne, Sir Walter Langdon-Brown, Sir John Ledingham, Sir Alexander Macgregor, Dr. R. Veitch Clark, Sir Francis Fremantle, Professors L. G. Parsons, Stanley Davidson, J. B. Buxton, and Dame Louise McIlroy. After outlining the scientific position, so as to bring the nature of the problem into focus for those who are unacquainted with the dangers of infected raw milk, the memorandum states categorically: "It has now been proved that the pasteurization of milk causes no material changes in the nutritive value of milk, that it does not injure milk in any way, and that properly carried out it destroys all tubercle bacilli and other pathogenic bacteria which may be found in milk. So treated milk retains its properties unharmed and is rendered safe to drink. Methods such as licensing, inspection, and the use of the phosphatase test are adequate to control the efficiency of pasteurization." None of the objections which the trade has raised can be sustained on scientific grounds, but three, two of them technical, are mentioned briefly in order to dispose of them. The memorandum recognizes that any scheme of compulsory pasteurization must cause some disturbances of existing practice, but these need not be such as to affect livelihood: it becomes simply a matter of the personal interest of a small body of traders against the health and safety of the community. While the League favours on scientific grounds the immediate pasteurization of all milk supplies, it considers that technical difficulties of application make immediate universal pasteurization impracticable. It therefore favours the following compromises: "(1) That any compulsory pasteurization order should for the present be limited to all urban areas over a certain population, such as 10,000, and also that during this period distributors who supply 'tuberculin-tested' or milk from 'attested' herds be not obliged to pasteurize their milk. The Order not to be made operative until after at least six months to allow time for the required plant to be obtained and adequate supervision arranged. (2) The smaller urban areas and rural areas to have the same powers after application to and approval by the Ministry of Health. (3) That after a suitable period these compulsory pasteurization requirements be extended to all milk supplies."

DESOXYCORTICOSTERONE AND FLUID METABOLISM

When desoxycorticosterone is given to patients with Addison's disease or to dogs with adrenal insufficiency, sodium is retained, and this in some cases may lead to an accumulation of extracellular fluid and even to symptoms of congestive heart failure. Such actions of desoxycorticosterone have been the subject of recent experimental investigations, and some interesting facts have been brought to light. In 1940 Ragan and others,[1] working at Columbia University, showed that daily injections of 25 mg. of desoxycorticosterone into normal dogs produced no excessive retention of sodium, but a pronounced polydipsia and polyuria developed instead, the daily fluid balance rising from a normal 400 ml. to over 1,000 ml. The specific gravity of the urine was lowered, and there was a slight rise in the concentration of sodium in the serum. Raising the sodium chloride content of the diet increased the fluid exchanges even more, so that daily intakes of 5 to 8 litres of water were recorded; equivalent additions of potassium chloride had no such effect. These symptoms obviously resemble those of diabetes insipidus, but the authors do not regard the conditions as identical, pointing out that pitressin was relatively ineffective in reducing the fluid balance of the dogs, and that when their water intake was restricted during treatment their urine output correspondingly diminished, so that symptoms of dehydration did not appear. Confirmatory experiments have been reported by Mulinos and his colleagues,[2] using doses of desoxycorticosterone acetate as low as 2 to 4 mg. a day. Their findings, however, differ somewhat in that total deprivation of water failed to restore the specific gravity of the urine to normal levels, and, although there was a decrease in the extent of the polyuria, thirst and other signs of tissue dehydration were produced. Although pitressin was less effective in inhibiting water diuresis in the "diabetic" dogs than in normal ones, these authors were able to reduce the fluid exchange and urinary chlorides of the treated dogs to normal by giving large doses of pitressin in oil. They regard the experimental condition as a true diabetes insipidus, and attribute any quantitative differences from the human condition to the presence in the animals of functioning posterior pituitary gland. Against this view is the authors' finding that polydipsia develops before polyuria in the treated dogs; this does not agree with previous experimental work on diabetes insipidus and is a qualitative rather than a quantitative difference.

The Columbia University workers later[3] investigated the electrolyte changes in dogs receiving daily doses of 25 mg. of desoxycorticosterone acetate. They had previously found that dogs which had received injections for a long period developed attacks of muscular weakness, with paralysis and eventual death. They now found that these muscular disorders could be prevented by the addition of potassium chloride to the diet, though this did not prevent the rise in serum sodium or increased fluid exchanges due to the injections. Analysis of the muscles of the dogs which received injections showed the sodium content to be nearly doubled and the potassium to be much diminished, while nitrogen, water, and chloride contents were unaffected. Apparently the sodium–potassium interchange was quantitative, one atom of sodium replacing one atom of potassium. These electrolyte changes did not occur in dogs fed on a high potassium diet, indicating that the actions of desoxycorticosterone on electrolyte pattern and on fluid metabolism are independent.

Corey and Britton have for some years been investigating the effects of adrenal cortical extracts on the fluid metabolism in the rat. They are strong supporters of the theory that the normal fluid exchanges of the body are regulated by the antagonistic actions of adrenal cortical and posterior pituitary hormones. They find[4] that hypophysectomy in the rat causes an immediate acute polyuria lasting 3 to 5 days, during which period the urine output exceeds the water intake. This is followed by a 3-day period during which polydipsia develops and water intake exceeds urine output. Finally, a chronic condition of mild diabetes insipidus supervenes with an approximately normal ratio between water intake and urine output. In this latter condition desoxycorticosterone acetate increases the fluid exchange proportionately more than it does in the normal rat; this increase is, however, abolished if pituitrin is given at the same time (0.25 unit of pituitrin cancels the effects of 2 mg. of desoxycorticosterone acetate). Supporting evidence for their theory is provided by their previous observation[5] that diabetes insipidus does not follow hypophysectomy if the adrenals are removed simultaneously.

Thus, while the evidence for the production of polydipsia and polyuria is conclusive, whether this action of adrenal cortical hormones plays any part in the normal regulation of fluid exchanges or in diabetes insipidus is not yet proved. The experiments in the rat are open to the objection that true diabetes insipidus as produced in dogs by Ranson and his colleagues was abolished when the anterior lobe of the pituitary was removed. On the other hand, the presence of posterior pituitary tissue in the injected dogs may well modify the symptoms produced by desoxycorticosterone. Be this as it may, Moehlig and Jaffe[6] have observed marked polyuria and polydipsia, with attacks of muscular weakness, in a patient implanted with pellets of desoxycorticosterone acetate. The symptoms developed when a tablet containing 150 mg. was crushed, causing an overdose of the hormone. The symptoms persisted for two months, demonstrating that the effects seen in animals may also be produced in man.

The Therapeutic Requirements Committee of the Medical Research Council, as announced in our issue of April 3, has again urged practitioners not to prescribe desoxycorticosterone acetate for any patients except those suffering from Addison's disease, because the supplies now available are only sufficient for that purpose.

The fourth international assembly of the International College of Surgeons will be held on June 14-16 at the Waldorf Astoria Hotel in New York City, under the presidency of Dr. Fred H. Albee. The programme will be devoted to war surgery and rehabilitation. Delegations made up of surgeons from the United Nations in addition to those from other countries are expected to attend.

HEALTH SERVICES IN INDUSTRY

GOVERNMENT CONFERENCE

The Ministry of Labour and National Service summoned a three-day conference in London, opening on April 9, on industrial health. It was attended by industrial medical officers and nurses, welfare officers, shop stewards, and others in different ranks of industry, who did not allow, as one of them put it, "the bigwigs to get away with their pious generalizations." One young girl, indeed, obviously impressed the Minister of Labour with her account of the conditions in a railway goods yard in North London, where 3,000 workers are employed, and where there is no first-aid room or surgery.

Mr. ERNEST BEVIN said that he hoped the Conference would crystallize the interest in this subject and evoke suggestions which might be taken by the Government and by industry during and after the war. He applauded the introduction of the works doctor, especially the part-time doctor who was also a general practitioner. A similar blessing was pronounced by Mr. ERNEST BROWN, Minister of Health, who said that if the background of all workers in the future was to include a full family doctor service run from properly equipped group practices it would be a wise policy to bring the doctors more and more into the medical supervision of factories.

The Works Doctor in the Future Set-up

Sir WILSON JAMESON, Chief Medical Officer, Ministry of Health, pursuing the same theme, said that the comprehensive medical service which the Government had decided to make available for everyone must direct its efforts towards positive health. It was unthinkable that the doctor who thus undertook the care of a family should have contact with them only after illness had occurred. Arrangements must be made for him to take over many of the duties which the more purely preventive public health services had performed in the past, and to do this he must have the help of the public health nurse and the social worker. All this called for changes, not only in the conduct of medical practice but in medical education. Medical students must be trained to think in terms of social as well as of individual medicine.

The place of industrial health services within a comprehensive medical service was discussed also by Dr. CHARLES HILL, Deputy Secretary of the British Medical Association. Now was the time, he said, to examine the set-up of the industrial medical service. If the task were left until after the war it might well be impeded by economy committees and the like. It was of no use pretending that the factory health service covered the sort of factories in which it was most needed. The majority of workers were in the smaller factories,* which as a whole were not covered by the service. The service was also to some extent prejudiced by the fact that it was an employers' service and the doctor was looked upon as the employers' doctor. He did not believe the prejudice to be justified, but a service so arranged must remain haphazard and incomplete. Until the factory medical service became part of a national environmental service it would not earn the right of continuance as an essential part of health machinery. He added that the medical profession regarded the development of industrial medicine as of profound importance. It was the development for which, perhaps, in the field of health, this war would be remembered, just as the last war was remembered for the Maternity and Child Welfare Act, 1918.

Education and Research

The training of the works medical officer was the subject of a paper by Lieut.-Col. G. S. PARKINSON, Dean and Director of Public Health, London School of Hygiene and Tropical Medicine. A diploma in industrial health, he said, might be a guarantee of a state of proficiency of medical officers entering industry. Before undertaking a postgraduate course in industrial health the medical man or woman should have spent at least two years in house appointments and in general practice. He suggested the following syllabus for industrial health training:

The working environment; nutrition, energy expenditure; industrial fatigue; medical industrial psychology (vocational guidance and selection); accident prevention and the psychoneuroses of industry; modern industrial system of labour management; organization of medical service in industry; methods of recording sickness and accident rates; bacteriology in industry; occupational diseases and poisons and their prevention; industrial surgery and rehabilitation; principles of industrial law.

In addition a period of practical training in selected factories should be provided in order that the future medical officer might see the conditions under which work was being carried out.

Sir EDWARD MELLANBY, Secretary of the Medical Research Council, pointed out that, however good the central or local administration might be, and however efficient the doctors, medical treatment could only be as good as existing knowledge permitted. The Industrial Health Research Board had assembled a collection of facts, especially relating to optimum health conditions, which were of fundamental importance, a collection unrivalled in any other country. Sir Edward added that when he first approached the work of the Medical Research Council on its industrial side he had in mind two great factors—namely, industrial hazards, especially in relation to new toxic solvents, and the psychological problems of fitting the man into the job. He now believed that the former would be a relatively small factor, and the latter a very large one. No subject was more important than industrial psychology, and none could be more gravely mishandled.

The Doctor in Dungarees

A lively speech was made by Dr. A. J. AMOR, Deputy Chief Medical Officer, Ministry of Supply. To deal with industrial fatigue, he said, was really a question of getting down to minutiae. The medical officer must leave his well-appointed surgery, get into dungarees, and go into the factory. He had seen committees investigating absenteeism with never a report from a keen, intelligent, human doctor who had gone into the factory and found out what was wrong. Industrial medicine was not a question of pills and powders and plasters but of painstaking study of environment.

Dr. Amor gave an account of the conditions in a Royal Ordnance factory where large numbers of women dealt with explosives which irritated the skin. During the last year the incidence of dermatitis here had gone down by 60%. An important feature of the factory was the "beauty parlour" adjoining the wash room, with its marble basins, good-quality soap, and separate towels. In the "beauty parlour" were tables with little pots of cream and powder and pledgets of cotton-wool, and with plenty of mirrors on the walls. A hundred girls at a time, in their neat caps and overalls, made up their faces as if they were going to a party, and then, bright and smiling, went to their work on detonators, the most dangerous work on which women were employed to-day. And, thanks not a little to the feeling of happiness and well-being, dermatitis had gone down by 60%.

Dr. R. E. LANE said that medicine could not live in industry as a luxury service, but only as an integral part of wise management and as one of the components of the medical service of the community. Dr. M. W. PATERSON spoke of the danger lest whole-time officers should be divorced from life and practice outside the factory. Dr. E. R. A. MEREWETHER, Senior Medical Inspector of Factories, said that occupational disease was preventable, and progress in that direction could be measured with certainty. The sum total of incapacity from known occupational diseases was somewhat exaggerated. In the five years before the war the total number of deaths from silicosis or from silicosis with tuberculosis was equal to 22.8% of the number of fatal accidents in factories and mines. Dr. W. BLOOD pleaded for a standard system of sick records and of periodical returns so that morbidity figures in different factories could be compared. Dr. G. DE SWIET spoke of the close integration of domestic and works conditions. The boundaries of industrial health were very difficult to define.

Among other points brought out in a discussion of wide range were the lack of facilities for the training of occupational therapists; the unduly heavy weight-lifting required of women in some factories; also the defectiveness of the eyesight of middle-aged women entering industry; the detrimental psychological effect of the crowded waiting-room of the panel doctor or the out-patient department; the need for a wider and more economic distribution of nurses specially trained in industrial health; and the need not only for the provision of food of nutritive value in the canteens but for the education of the worker in his food preferences.

---

* Sir Wilfrid Garrett, Chief Inspector of Factories, told the Conference that, just before the war, 32.2% of workers were in factories in which up to 100 people were employed, and 18.8% in factories in which there were over 1,000 workers.

Mr. BEVIN, in closing the Conference, referred to the problem of the adolescent worker. He thought it would be found, when the new Education Bill was introduced, that provision would be made for carrying the School Medical Service to a higher age and making it universal. The break in continuity of medical oversight on leaving school should not be allowed to remain.

EUROPEAN ASSOCIATION OF CLINICAL PATHOLOGISTS

At a meeting held in the Medical School of University College Hospital, London, on April 3 a European Association of Clinical Pathologists was inaugurated. Between twenty and thirty medical men and women drawn from Austria, Belgium, Czechoslovakia, France, Germany, Great Britain, Hungary, Italy, Poland, and Russia were present.

Dr. F. PICK of Prague said that since coming to this country he had been impressed by the conception of clinical pathology as practised here, and he believed that this represented a method of approach to medicine which might with advantage be developed on the Continent of Europe when the present troubles had come to an end. He called upon Dr. S. C. Dyke, former secretary and president of the British Association of Clinical Pathologists, to take the chair and to explain to the meeting how clinical pathology was organized in this country.

Dr. DYKE pointed out that clinical pathology, although a special branch of medicine, was within itself unspecialized, and permeated and had relations with all branches of medical practice. He described how the British Association of Clinical Pathologists had come into existence. Owing to the relatively unspecialized nature of its proceedings, he said, its meetings formed a peculiarly happy ground for the free interchange of views between practitioners in the various branches of medicine. He hoped that some of those present, on their return to their own countries, would organize national branches of a European Association in their own countries; and he believed that the British Association, having been the stock from which the European Association had sprung, would willingly become a branch. Dr. Dyke then moved from the chair that "there be formed a European Association of Clinical Pathologists."

Prof. E. J. BIGWOOD of Brussels stressed the importance of establishing contacts between clinical medicine and the laboratory. Dr. M. MAIZELS hoped that after the war it would be possible to arrange for interchange of laboratory workers between clinical pathological laboratories in this country and those on the Continent. Dr. Dyke then read a letter of welcome from Dr. A. F. S. Sladden, President of the British Association of Clinical Pathologists, and resolutions from the council of the association offering the hospitality of all its meetings and gatherings to the members of the European Association. Dr. P. N. PANTON emphasized the need for a class of medical practitioners capable of taking charge of hospital laboratories; he had found medical laboratory workers from the Continent to be specialized to a degree which made it difficult for them to do this.

The meeting appointed a committee consisting of Drs. B. L. Della Vida (Rome), S. C. Dyke (Oxford), M. Mandelbaum (Munich), F. Pick (Prague), F. Silberstein (Vienna), and J. Ungar (Prague) to draw up rules and to submit them to a further meeting to be held in London some time in May. Dr. Pick was appointed secretary, and all who are interested in this new organization are asked to communicate with him at the Department of Clinical Pathology, the General Hospital, Walsall, Staffs.

NAVAL SURGEON'S HEROISM

References to the heroism of the medical officer in a British destroyer have appeared in several of the newspapers. The *Times*, in a very full account, states that this officer, Surg. Lieut. Philip Raymond Charles Evans, R.N.V.R., was serving in a British destroyer which picked up most of the survivors of the Canadian corvette *Weyburn* when she sank on her way back from the Mediterranean. He was standing on the destroyer's deck, helping survivors of the *Weyburn* from the water and attending the wounded, when the corvette went under and his legs were broken below the knee by a second underwater explosion which followed her disappearance. Without thought for his own severe injuries he insisted on being carried round the destroyer's decks to attend to the slightly wounded there. Then he asked to be taken to the wardroom, which was filled with men injured by the second explosion. He was placed in a sitting position on the floor beside each cot, and from there he examined the men, giving orders for treatment to the sick-bay attendant. In spite of the pain he suffered every time his legs were moved he insisted on carrying on without rest. Only when every examination had been made did he allow himself to be placed in a chair with his legs stretched out straight in front of him for what small measure of comfort was possible. He still refused to stop work, and sat in the chair for 12 hours, until the destroyer reached Gibraltar, directing the treatment of several men seriously wounded or burned. In all he attended more than 50 injured and wounded seamen.

Reports of Societies

ATYPICAL PNEUMONIA

At a meeting of the Section of Medicine of the Royal Society of Medicine on March 23, Dr. GEOFFREY MARSHALL presiding, the subject of atypical pneumonia was introduced by two officers of the U.S. Army Medical Corps.

American Army Experience

Capt. JOHN W. BROWN said that since about 1935 several papers had been published describing an atypical pneumonia, mild in character, from which the patients with rare exceptions recovered. Very occasionally, however, a highly fatal condition developed; thus in San Francisco in 1940 a patient died in hospital from this disease after infecting his three nurses, two of whom died; two doctors in attendance also caught the infection and both were ill for several months. The disease had been referred to by different names, such as disseminated focal pneumonia, acute diffuse bronchiolitis, and pneumonitis, but it had been now more or less agreed to call it primary atypical pneumonia (aetiology unknown). The onset was usually insidious; the symptoms were almost identical with those of influenza but the fever lasted longer (from 7 to 15 days), and *x* rays showed patchy lesions in the lungs, mostly beginning at the hilum and spreading to the periphery. Chemotherapy did not affect the course of the disease. An extensive study of the possible aetiology had been made. In some of the cases the rickettsia bodies of acute fever had been found, and in a series of 50 cases in his own experience 3 had shown a rise of antibodies to psittacosis virus. But most of the outbreaks failed to reveal any particular agent. Since July, 1942, at his hospital in this country there had been 102 cases, all of them in soldiers; the number was equal to two-thirds of the total number of pneumonias. No epidemiological significance was attached to them, in the sense that no large group of cases came from any one unit.

Lieut.-Col. GORDON E. HEIN said that they as American medical officers were in an exceptional position in this respect, that the patients with whom they had to deal came in most cases from parts of America far distant from the parts from which the M.O.s had come themselves, so that their previous civil experience was of no particular avail, and the patients were in an entirely different environment from that of their own homes, and unavoidable crowding and community living had enhanced exposure to bacterial and virus agents. The 102 cases seen in hospital during the last eight months had been all more or less similar; they certainly differed from the cases of pneumococcal pneumonia, and also were quite different from the cases seen during the influenza pandemic of 1918. The patient himself might not feel ill, pyrexia might be slight, cough moderate, the sputum was not blood-stained as a rule, and mental confusion was not a prominent part of the picture. He brought forward for elucidation four cases which were "atypically atypical"; two of them developed meningo-encephalitic symptoms, and the other two had an unusually prolonged fever after the pneumonia had disappeared. One of the former two was as follows:

A man aged 22 was admitted to the orthopaedic service because of an old shoulder injury. After being in hospital 23 days he developed pneumonia, marked by malaise, a non-productive cough, and fever, but no frank consolidation. His temperature rose to 102°, and, after falling, rose again to 104°, at which point it remained for three days. On the fifth day of the illness he was somnolent and unduly sensitive to light, and his neck was stiff. The temperature began to drop and within two days was normal. One week after onset of the illness all evidence of pulmonary inflammation had disappeared, but the spinal fluid remained hazy, and the patient still had somnolence, photophobia, and stiff neck. All symptoms disappeared eleven days after onset, but spinal-fluid changes remained longer. He entirely recovered.

British Experience

Dr. Geoffrey Marshall said that at periods, perhaps ten or fifteen years apart, there occurred groups of these curious anomalous types of pneumonia. He agreed that the cases occurring now were quite different from those seen in France in 1918, in which there was an extremely high mortality. It seemed to be characteristic of the atypical case that the patient was ill, and after perhaps a week or two got a rigor or chill and developed this pulmonary lesion. In most cases the illness was over within about 10 days, but how long the shadows revealed by x rays persisted he could not say.

Col. W. R. M. Drew said that during the last two winters some 40 or 50 of these cases altogether had been seen at two military hospitals. They presented very much the same picture as had just been described. In some of them the lung lesions were extensive and yet there were very few clinical signs. The lesions sometimes seemed to move from place to place in the lung, but in practically none of the cases did they persist for longer than two or three weeks. In the few cases in which there was opportunity to make an examination of the sputum and a blood culture these were negative. No such complication as meningo-encephalitic symptoms or prolonged fever had been noted, nor was there any marked debility afterwards.

Major E. Samuel said that radiologically the picture in these cases did not conform to that of bacterial pneumonia. A large number of the patients were ambulatory and afebrile, and the difficulty in the radiograph was to differentiate between an early tuberculous lesion and a patch indicative of primary atypical pneumonia. A quite common site for the lesion in these cases was just beyond the apex of the heart in the left lower zone of the lung.

Col Montgomery (Canadian A.M.C.) referred to the difficulty of nomenclature. In his position as consultant he had been almost able to decide from which hospital a case was referred by the name attached to it. In a short series of 47 cases none of the complications to which Col. Hein had referred had been noted. If the patient's temperature was normal within 10 days and a radiograph was not taken it would probably not be known whether he had had pneumonia or not; but if pyrexia persisted for over 10 days one could be almost sure of seeing a lesion on x-ray examination. Dr. F. H. Young said that he had seen patients with pictures like this who were sent up to Brompton Hospital "query tuberculosis," and by the time arrangements could be made for them to be received as in-patients the radiological lesions had disappeared. In no case of this type had he been able to find any abnormal signs at all. Dr. Livingstone said that he had not seen many of these cases, but at the beginning of the war 50 or 60 cases of supposed influenza were received from the Guards depot. They were not x-rayed, but his recollection was that not a single one of them showed prolonged fever. The suggestion of psittacosis virus was rather startling in view of the number of people who now kept poultry.

A Cyclical Disease?

Sir Henry Tidy said that at St. Thomas's these cases began to be seen from 1935 onwards. They were increasing before the war, and many physicians were recognizing them. An interesting question was whether this was the return of a disease which had been noted under a different name in earlier years. At about the period 1908-10, when he was working as a pathologist, there was a dispute between pathologists and clinicians because the latter used to diagnose central pneumonia and the former never saw it at necropsy. It was possible that in the literature at that time cases could be found which corresponded to those now seen, but after that the condition appeared to die out until 1935 or so. He was in Berlin about 1911-12, at a time when the physicians there had discovered a specific against the pneumococcus (which, however, proved to be too toxic), and a hospital in the German capital had an enormous number of cases of pneumonia, but he was quite certain there was nothing of this type then.

Dr. Philip Ellman and Dr. Gregory Kayne both showed a series of radiographs of lung appearances in cases which had come within their experience. Dr. Ellman suggested that a non-stereotyped pneumonia should properly include a broader classification of pneumonic conditions than the cases referred to so far in the discussion. Dr. Eli Davis referred to three cases in which the x rays showed consolidation of the lower half of the right upper lobe, and yet in none of the three were there any physical signs whatever in the whole course of the illness. Dr. Wilfred Oakley mentioned a case which corresponded almost exactly with Col. Hein's description of his two cases of meningo-encephalitis associated with atypical pneumonia.

Dr. Horace Joules said that at the Central Middlesex Hospital, which served a population of approximately a quarter of a million, there had been 58 cases of pneumonia admitted since the middle of December. Of these, about 28 had true lobar pneumonia and gave a typable pneumococcus; 17 had demonstrable consolidation clinically and radiologically, but it had not been possible to get a typable pneumococcus from them; while 12 had had the clinical condition now described as atypical pneumonia. His problem was with regard to the 17. How far should the search go? The sputum and blood culture had been persistently negative. Should lumbar puncture be done in all cases? In some of the pneumococcal cases the organism had not been obtained from the sputum but had been obtained from the blood. Many of these cases had had sulphapyridine before coming into hospital, and it might be that this had sterilized the sputum. The cases with prolonged pyrexia had numbered only two, but both of these had had the typable pneumonia.

THE RED CROSS: PRINCIPLES AND ORGANIZATIONS

At a meeting of the Section of History of Medicine of the Royal Society of Medicine on April 7, with Sir Walter Langdon-Brown presiding, Dr. A. P. Cawadias presented a paper on "Red Cross Principles and Organizations in the Light of History." He pointed out that the Red Cross was not in its origin purely humanitarian. It helped the war effort of every nation. It was to the interest of every belligerent nation to save as many as possible of its wounded, but equally to destroy as many of the enemy; but that was too narrow, even from the military point of view, for acceptance as a working principle, and a country could only help its own prisoners and civilian population by a mechanism which similarly helped those of the enemy.

Dr. Cawadias said that the Red Cross originated in the sixties of the last century. It was not true, as some histories affirmed, that the Knights of Malta introduced the Red Cross. The Knights, although they built hospitals and cared for the sick, were, first and foremost, warriors, and indeed at one time were a great military power. But not until after the Red Cross was established at Geneva did the Knights of Malta, with their headquarters in Rome, and the Order of the Hospital of St. John of Jerusalem, begin to do Red Cross work in the sense of helping wounded soldiers and civilian populations independently of nationality. He then described the work of Henri Dunant, member of a patrician family in Geneva, who in his book published in 1862 set out the principles of the Red Cross. A name which also deserved prominence was that of Gustave Moynier, a Genevese lawyer, who instituted the first Red Cross Committee, which in turn led to the calling of the first international conference, opened by General Dufour in Geneva in 1863 and attended by representatives of sixty countries. The Red Cross had its baptism of fire during the Russo-Austrian War of 1866; Austria at that time had not adhered to the Red Cross convention, but Russia had done so. At the time of the Franco-Prussian War the French, unlike the Prussians, had not developed the Red Cross principle. The Red Cross then applied only to wounded soldiers; at a subsequent conference the principle was enlarged to take in sick soldiers as well, and later was extended to naval warfare and prisoners of war, then to civilian populations in wartime, and finally to those suffering from calamity in peacetime. To-day there were 57 Red Cross societies, and there had been 16 international conferences.

One of the first essentials for the future of the Red Cross was an established international organization. No one knew whether there would again be a League of Nations in Geneva, but a League of Red Crosses in Geneva there should certainly be. There was need for stronger centralization and more support in each country for its national Red Cross, with an elimination of the divisions existing in some countries between those doing Red Cross work.

Sir WALTER LANGDON-BROWN said that the division between the Red Cross and the Order of St. John had in the past led to overlapping and even to real friction. It was the only criticism he had to make of those two organizations, which had done such gallant work. Mr. H. DE POURTALES, a delegate of the International Red Cross Committee, who is inspecting the prisoner-of-war camps in this country, said that it was essential to the Red Cross movement that it should steer clear of all political intervention. It was only because of its freedom from politics that it had been able to develop its organization. He described the work in Geneva, where 3,000 were now employed, about half of them on a voluntary basis. They were in touch with practically every belligerent country—not quite all—and had been able to answer inquiries about the conditions of prisoners and to send relief. Mr. F. CAMBRAY, also attached to the Red Cross organization, mentioned the organization of parcels for prisoners of war, and also the arrangements for certain prisoners in German and Italian hands to take professional examinations.

Dr. CAWADIAS said that this time there were practically no neutral national Red Cross committees, and the whole strain had fallen on the International Committee, so that a few citizens in Switzerland had found themselves under an obligation to look after the whole world. When the history of this war came to be written the fame of that International Committee should be in letters of gold. The Red Cross organization would not cease with the armistice. Every effort that it could make would be required for the relief of Europe.

FACTORS INFLUENCING LACTATION

The fifth scientific meeting of the Scottish Group of the Nutrition Society was held in Glasgow on Feb. 20, when the subject discussed was "Factors influencing Lactation and the Nutrition of the Infant."

Prof. G. B. FLEMING, who was in the chair, said it was strange that natural selection had not produced a higher percentage of good milkers among women, particularly when account was taken of the high mortality rate of the artificially fed even as late as the middle of the last century. A qualitative alteration in the milk was of far less importance than a quantitative deficiency; it was better for the infant to be nourished by an undernourished mother than artificially fed, provided the quantity of milk available was sufficient. Milk production was influenced by diet, fluid intake, emptying of the breast, and frequency of milking, work, and nervous factors.

Dr. J. A. B. SMITH, in a paper on the effect of diet on lactation in animals, first pointed out that the proportion of glandular to connective and fatty tissue in the lactating gland influenced lactation. Unless the gland was fully prepared for milk secretion during pregnancy efficient lactation could not be expected, however adequate the diet. With the well-formed gland maximum lactation could only result if the diet was sufficient in energy, protein, and vitamins. Owing to an increase in the basal metabolic rate during lactation the energy of the additional digestible nutrients allowed for milk production must be almost twice as much as the energy in the milk. The protein supply must be of first-class biological value and rich in lysine and cystine. At the height of lactation the cow was usually in negative calcium balance, but this had no deleterious effect on the yield or quality of the milk, provided the feeding during pregnancy and in later lactation was adequate for the calcium stores to be replenished. Milk with maximum vitamin content could be obtained only by a liberal allowance of vitamins in the diet.

Dr. G. H. BELL, describing hormonal influences on lactation, said that preparation for lactation began early in pregnancy, and oestrogen and progesterone were not sufficient in themselves to bring out the full development of the mammary glands; presumably the anterior pituitary as well as the ovaries were involved. During pregnancy lactation might be inhibited by the large amounts of oestrogen in the circulation. After parturition the oestrogen secretion ceased, and the pituitary hormones could then initiate lactation. Prof. CHARLES MCNEIL dealt with nutritional defects in hospital infants, a subject to which, he said, too little attention was paid in the teaching schools. He described the advantages of breast-feeding and the need for expert management in the first month after birth.

Prof. J. HENDRY, who had studied the extraneous factors influencing satisfactory lactation in some 165 women from two social grades, emphasized: (1) that provision should be made for employed and for unmarried mothers to fulfil their obligations to their children despite their work commitments; (2) the importance of a successful first lactation and of preventing mastitis and other complications leading to tender breasts; and (3) the need for ante-natal care in preparation for lactation, and of continued supervision and care of the mother when she returned to her normal duties at home. Measures should also be taken, he said, to stop some maternity nurses in better-class homes giving selfish advice which led to premature cessation of breast-feeding. Dr. JEAN MACINTOSH, in some observations on the relative incidence of breast and artificial feeding, stated that recent surveys indicated that 50% of women breast-fed their infants up to the age of 3 months, but by the time the child was 6 months this figure had dropped to 40%. There was less breast-feeding among mothers in poor districts than among mothers in nursing homes. Dr. Macintosh excluded diet as one of the main causes of this, since breast-feeding had declined slightly in spite of an improvement in general nutrition. Psychological influences undoubtedly played a part, she said, but evacuation and air raids had not apparently affected the lactation of many women subjected to these disturbances. Dr. STANLEY GRAHAM described an investigation among some 300 infants under 18 months admitted to a medical unit at the Royal Hospital for Sick Children, Glasgow, over a 12-month period. Some 66% were less than 90% of their expected weight, and at least 50% suffered from iron-deficiency anaemia. On clinical and radiological grounds 25% showed evidence of rickets, and on biochemical grounds 40%. These nutritional defects, which predisposed to infection, could undoubtedly be greatly reduced by adequate feeding. This in turn would lead to a material reduction in the morbidity and mortality from such infections as gastro-enteritis and bronchopneumonia.

In the discussion which followed, Dr. A. B. ANDERSON described a case of lactation tetany following 21 months breast-feeding. The serum Ca had fallen to 6.9 mg. per 100 ml. When lactation was stopped and the patient was given a good diet the tetany cleared up. The CHAIRMAN gave data to show that there was no evidence of increased iron deficiency in a poor-class infant clinic as the result of war.

MILIARY TUBERCULOSIS

At a meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland in February Dr. G. T. O'BRIEN showed *x*-ray films and gave the histories of two cases of healed miliary tuberculosis. The radiographical appearance of one of these resembled that of bronchopneumonic phthisis; but the appearance of the other case was that of miliary tuberculosis. Both cases had been observed over some years, and both clinically and radiologically they appeared to have greatly improved over that time.

Dr. DOROTHY PRICE reported two cases of healed chronic miliary tuberculosis. One was that of a child of 1½ years who had been under treatment for 5 months. There was now *x*-ray evidence of calcification of the multiple lung foci and primary complex. Spinal caries and psoas abscess also appeared to be healed. In this case the human type of tubercle bacillus was found in the gastric washings during the active stages. In the second case the patient when 10 months old was treated in hospital for a primary lung complex, and 8 months later developed bilateral miliary tuberculosis of the lungs, with pleural effusion. A year later the miliary tubercles were healed "without radiological residue," and calcification of the primary complex had begun; to date there were no secondary metastases outside the lungs. Dr. Price attributed healing (not yet completed) to the very long period of recumbency under good hospital conditions, which was the sole treatment; and emphasized that relapses with fatal termination reported in the literature occurred when the patient resumed exercise too soon. The bed rest should be continued until radiological evidence of calcification was assured; no regard should be paid to temperature and sedimentation rate, which were normal long before foci were healed. Clinically, it was at first impossible to distinguish between acute and chronic miliary tuberculosis. Pathologically the lesions were the same, the acute being probably due to massive and repeated infections of the blood stream by the bacilli; in the chronic, single or small quantities were released.

The PRESIDENT said he would be inclined to question some of the healed cases. He would like to know about the sputum examination in both cases. It was thought that miliary tuberculosis in the child always took an acute form. Dr. Price's findings were radiological rather than clinical. Dr. W. R. F. COLLIS said Dr. Price had done much for these early cases.

Dr. R. E. STEEN stressed the subject from the point of view of prognosis. Some people regarded miliary tuberculosis as hopeless. He had a case similar to Dr. Price's which did well. It was not possible always to give a dogmatic prognosis from an *x*-ray film of the chest. In none of these cases was there enlargement of the spleen. Dr. A. R. PARSONS considered that the diagnosis of these cases appeared to be passing into the hands of the radiologist. They were a most interesting series of cases, but not a single one had tubercle bacilli in the sputum. He had always looked on miliary tuberculosis as fatal.

Correspondence

Value of Study Groups

SIR,—It seems clear from pronouncements by various Government speakers during the past few weeks that the profession will have reasonable time to consider and discuss the steps and methods whereby a scheme for comprehensive health, etc., can be initiated. It is of vital importance that all practitioners should be kept informed of the progress of the deliberations taking place, and also should be encouraged to express their views at medical meetings and enter into informative discussions. In order to attain this end, fuller use must be made of the Study Groups which proved so successful last year, and a satisfactory method of co-ordinating and correlating their results should be devised. At present there is a sense of frustration among the rank and file that the views expressed at the Study Groups do not get anywhere, and so these discussions are largely a waste of time.

I suggest that the views of the Study Groups should be conveyed to the Council of the B.M.A. through co-ordinating committees, using the minimum number of steps, and so far as possible utilizing the machinery already available—e.g., Study Groups to local co-ordinating committees, which might be the local B.M.A. executive committee, thence to area committees, and so to the Council. There are two necessary factors for the success of this scheme.

(1) All members of the profession must be invited to local Study Groups, and every effort must be made by local organizations to see that the Group meetings are well attended.

(2) It is necessary that each Study Group should elect at least one member to the co-ordinating committee, and so on from this committee upwards. This will help to ensure an even flow of opinion from the lowest group to the highest.

Let the Study Groups be placed firmly on the medical map. I am sure they will fill an obvious gap in the present organization, and now deserve official recognition. They are an excellent means for testing out opinion on dubious points, and also help to satisfy the disillusioned leech who says, "Nobody listens to me."—I am, etc.,

Birmingham. R. C. L. BURGES.

Undisclosed Government Plans

SIR,—I am writing to you concerning an article on the "National Health Service" which appeared in the *Times*, of April 12. This, I suppose, must be taken as a kite flown by the Government to see which way the wind blows in relation to plans it has prepared but not yet disclosed. It appears to me that the Government is likely to embark on a very ill-advised course. The tradition of medicine has always rested upon the unlimited responsibility of the doctor towards his patient (this is the Hippocratic position) and upon the status which the practitioner has consequently acquired. It is true that there are and have been bad doctors, but none the less the quality of doctoring has been maintained by unlimited therapeutic responsibility and the maintained status of the practitioner which alone makes such unlimited responsibility practicable.

The considerations which now appear likely to be put forward concern administrative convenience. The purely medical thing is to be put under the suzerainty of the purely governmental thing. If this is allowed to come to pass a disaster will have been achieved. Since it is necessary to co-ordinate (even, it may be, to control) medical practice, the essential is that such co-ordination shall spring from the very quality of what the doctor is and does. Those who know this quality from their experience of the art of practice—I refer to the intimacies of personal consultation—must be in a position to secure, to govern, and to endow their fellows with the conditions which favour their art. The medical officer of health, as the representative of the local authority, is already too far removed from the heart of medicine. The clinic has still to find the way by which it can render to the person and to the family that which will promote their quality and development. If in the new health service the best traditions of medicine are to survive, kindly personal relationships between medical men must not be substituted by the boss who issues the pay packet and administers the necessary discipline.—I am, etc.,

Coventry. K. E. BARLOW

Partnership or Bondage?

SIR,—I welcome the last part of your leader in the *Journal* of April 10 (p. 449). It points clearly to some unity of views between the rank and file of the profession and those who have our affairs in hand. Recent correspondence and the editorial referred to suggest that the profession as a whole realize that we can trust the airy utterings of the Ministry of Health as a wayfarer would trust an empty boa constrictor who has given ample warning of its intentions.

We cannot easily forget: (1) the evidence of the "regional medical Gestapo" at the Arbitration in 1937; (2) the unilateral extension of the Panel; (3) the repeated refusal of the Ministry for a reasonable and long-overdue increase in the capitation fee; and (4) the dissimilarity between the letter of the Ministry to the B.M.A. suggesting "building from the basement" and the public announcements of the same Ministry of obviously preconceived ideas.

In fact, our previous dealings with the Ministry show that we shall have to get up very early in the mornings indeed if we are at least to keep pace with its moves, and that to counter the horseshoe in the Ministerial boxing-glove we must have not only unity but also a knuckle-duster under our kid glove. The Minister must be made aware that while the profession is capable of giving continuous medical service to the nation, even without a N.H.I. scheme, the Minister is not in any position to alter the medical services without our co-operation; and that while the profession may be willing to enter into partnership agreement with the Ministry for the common weal, we are not prepared to sell ourselves into bondage on any terms.—I am, etc.,

Ashton-in-Makerfield. PERCY GONSALVES.

Psychological Factors in Alimentary Tract Dysfunction

SIR,—The articles by Sir Arthur Hurst and Dr. C. H. Rogerson on asthma in childhood strongly suggest a close analogy between asthma and the alimentary tract dysfunctions, particularly the group characterized by spasticity of the colon, mucous colitis, and their congeners. Although these conditions often do not develop until middle life, the personalities of the sufferers show a strong similarity to those described by Sir Arthur Hurst and Dr. Rogerson, and there is no doubt a physical and psychological diathesis which predisposes to these conditions.

Sir Arthur Hurst makes the point that conditions that at one time will produce an asthmatic attack at another are perfectly harmless, and this is also true of the colon dysfunctions. In view of this fact the treatment of such cases by dieting needs to be carefully reviewed. Patients and doctors have a tendency to cut out of the diet any form of food which appears to have precipitated an attack. The result is that many patients are definitely undernourished, taking an ill-balanced dietary defective in essential vitamins and minerals. It is not uncommon to hear such patients say that attacks occur from time to time even when they are rigidly keeping to a very limited diet, just as an asthma attack will sometimes occur without any apparently incriminating factors.

There is no doubt that in all these conditions treatment should be undertaken from both the physical and psychological aspects, so that the vicious circle set up may be broken at two points. It would indeed be desirable that the doctor who treats the patients' physical symptoms should be able to treat them from the psychological aspect also, but, unfortunately, relatively few general practitioners have either the time or the training necessary for this. This is only another illustration of the close interpenetration of physical and psychological factors in health and disease.

May I also say a word on another subject—i.e., the report of the Conference of the Ex-Services Welfare Society on War Stress and the Incidence of Neurosis. The report omits valuable conclusions which were arrived at: (1) That it is essential to devise some machinery whereby people discharged from the Forces for psychiatric reasons could be put in touch with their own doctors and/or with a local psychiatric clinic, or, when these are not available, with suitable psychiatric social workers, as otherwise they simply drift and deteriorate still further. (2) That such cases and those of civilians referred to clinics for psychiatric treatment need also facilities for paid employment of a specialized type or under specialized conditions, in order to rehabilitate them. Psychotherapy is not sufficient, as they need work to stabilize them by restoring their self-respect and self-confidence and by reducing the anxiety of financial stringency and dependence.

The need was referred to in the Tomlinson report and cannot be too strongly stressed. It is frequently impossible to send a man to a full-time job without his breaking down again; there is no light or part-time work available, and consequently he does not benefit from psychological treatment, or at best only to a very limited extent.—I am, etc.,

London, W.1. DORIS ODLUM.

Extending the Use of Collapse Therapy

SIR,—Many will endorse Dr W. D. W. Brooks's plea (April 3, p. 423) for the more extensive use of collapse therapy to shorten the duration of the average stay in a sanatorium, and thus help to reduce the growing waiting-lists. This would involve not merely collapse therapy for some patients to whom it is not now applied but also initiating it earlier in others, and shortening the intervals between successive procedures that may be required to make the collapse effective. In encouraging these principles one thing must, however, be borne in mind. Collapse therapy should not be initiated in sanatoria that do not have facilities for carrying out, immediately they are needed, those accessory or consequential measures that may be required to obtain effective collapse, as, for instance, adhesion-section. If pneumothorax is to be attempted more often in such institutions then the axiom should be to abandon, at the earliest possible moment, pneumothoraces that are not fully effective; for it is well established that contraselective collapse increases the danger to the patient, and will eventually lengthen the stay in institution. Our advice should therefore be to increase the use of collapse therapy only in those sanatoria that already have full surgical facilities. The few available thoracic surgeons, who already appear to have their hands quite full, may make even this modified policy impracticable at present, and more physicians should therefore perhaps be encouraged to learn and carry out adhesion-section and phrenic interruption. We need not be perturbed by such a practice, since we have had in this country, among physicians, at least one brilliant exponent of adhesion-section, and I personally know several superintendents of sanatoria who are doing excellent work of this kind.

Dr. Brooks also adds that "experience has shown in the U.S.A. and elsewhere that collapse therapy in ambulant patients is practicable and satisfactory from the patient's point of view and from that of public health." I was inclined until quite recently to believe this myself, but the following extract from the excellent book by Chadwick and Pope, U.S.A., *The Modern Attack on Tuberculosis*, compels caution. This is what they say: "The success of pneumothorax treatment under sanatorium conditions and its continuation in suitable patients after their discharge gave rise about 1935 to a wave of enthusiasm for ambulant pneumothorax as a substitute for sanatorium treatment. A number of cities established pneumothorax clinics where collapse was instituted and refills were given for patients who in many cases were encouraged to continue the treatment at home. In certain cases the results appeared to be satisfactory and the material saving in costs was cited as justification of the procedure. In the course of the next two or three years, however, the number of cases of empyema which developed in patients receiving ambulant pneumothorax convinced even most of its advocates of the inherent dangers of this procedure as an independent method of treatment. Physiologically it ignores the essential role of rest in the treatment of active tuberculosis and rationally should be limited to patients whose collapse has been safely established in the sanatorium and whose disease is sufficiently stable to justify the amount of exertion involved."—I am, etc.,

Staines. G. GREGORY KAYNE.

Treatment of Scabies

SIR,—I have read with interest Dr. J. R. Graham's article on the treatment of scabies (April 3, p. 413), and whole-heartedly agree that the routine disinfection of fomites is unnecessary and, in addition, expensive.

During an approximate period of 11 months commencing in February, 1942, 982 cases of scabies were treated in Blaydon, Ryton, and Whickham (868 with benzyl benzoate) without recourse, other than in two early cases whose owners insisted, to disinfestation of fomites, and the true recurrence rate was only a fraction of 1%. Such observations are, however, by no means original, and merely tend to accentuate the exemplary lesson on the subject given by that eminent dematologist Ferdinand Hebra in 1868, which, though occasionally referred to, is worthy of wider dissemination.

> " But in my judgment (which, however, I admit to be provisional)," states Hebra, " all these precautions are unnecessary. In the General Hospital of Vienna, where 1,500 cases of scabies come under treatment every year and are cured, the relapses never exceed 1%. Yet in this establishment no measures of disinfection whatever are employed, although we have both an oven and a vapour-bath such as are above described, which we could easily use if it were thought desirable."

It is indeed remarkable that Hebra's considerable observation should have been so easily forgotten or disregarded by all but a few, and is almost on a par with the controversy which raged as to the causation of the disease, conclusively settled by Renucci in 1834 and subsequently disbelieved by more than a few.

It has been shown on several occasions that fomites under favourable conditions may produce infestation, but compared with prolonged bodily contact (ideally in bed) such incidence may be ignored in face of the much bigger and more important issue. Like Carslaw (*Journal*, 1941, **1**, 648), I am not satisfied that one " efficient " application of benzyl benzoate will cure every case of scabies, since my own experience leads me to a somewhat different conclusion. It is one thing to extract dead mites (presumably mature females) at the end of a week and another thing to be sure, without a subsequent " follow-up " at least 3 weeks after the last application of the medicament, that all eggs and larvae have likewise succumbed.

Finally, it cannot be too emphatically stated that, following upon efficient treatment, true relapse is uncommon, whereas eventual reinfection traceable to an immediate source, usually familial and concealed, is comparatively frequent and in my districts has been estimated at 5.3%.—I am, etc.,

T. M. CLAYTON,
M.O.H., Blaydon, Ryton, and Whickham U.D.C.s

Tanning for a Skin Lesion

SIR,—At an operation for intestinal obstruction due to a pelvic abscess in a very seriously ill male patient aged 37 the ileum had to be drained. A de Pezzer catheter was introduced into the gut and fixed in the usual way. In a few days the wound in the region of the catheter broke down, and in spite of every effort to prevent it the intestinal contents leaked over the abdominal wall. A few days later the catheter came away and the flow became quite uncontrollable. By this time all the skin of the abdomen below the umbilicus and the skin of the groins and scrotum was involved. Pain was intense and persistent and the patient's general condition rapidly deteriorated, due in the main to lack of rest and sleep. Sedatives, including morphine, had little or no effect. Anaesthetic ointments, serum, Unna's paste, etc., proved useless in the treatment of the skin condition.

Struck by the close resemblance of the skin lesion to that of a second-degree burn after removal of the blisters, I decided to try tanning. A thick layer of "tannafax" was therefore applied and the result was entirely satisfactory. Pain disappeared almost immediately and the skin rapidly healed. At first the tannafax was applied every four hours, but as the fistula gradually closed, once a day.

The fact that I have been unable to find any reference to this method of treatment in the literature of the subject is my excuse for this letter, and I hope that any others who are induced to try it may achieve an equal success.—I am, etc.,

Royal Victoria Hospital, Belfast. K. A. MCCAUGHEY, Resident Medical Officer, Musgrave Clinic

Treatment of Asthma in Childhood

SIR,—Sir Arthur Hurst (April 3, p. 403) conspicuously abstains from making any reference to atropine among various asthma treatments. May I venture the suggestion that the old practice of administering this vagal depressant will be reinstated by the use of its less toxic derivative, atropine methylnitrate (eumydrin).

I had lately the opportunity in general practice to attend 3 children (of different families) between the ages of 5 and 9 suffering from attacks of bronchial asthma. All were old asthmatics who had gone through various forms of treatment. The following medicine was given: atropine methylnitrate 1/2 gr., water to 10 oz.; 1 to 2 teaspoonfuls 3 to 4 times a day. The medicine was uncoloured and unflavoured to exclude psychological effects so far as this is possible. The attacks stopped in all cases within a few hours, and it was possible to keep the children free from further attacks by the occasional exhibition of 1 to 2 teaspoonfuls of the above medicine at the first sign of "wheeziness." No further cases were treated. No untoward effect has been observed, and both mothers and children seem to prefer this treatment to all previous ones.

There is no doubt that atropine methylnitrate was active in these cases, as it was bound to be considering the high dosage employed. On the other hand, I am fully aware that the recorded number of cases is far too small and the reference to previous treatments far too vague to give any indication as to the relative value of this treatment. I shall be grateful for references to clinical work done on this line and, in the absence of such, I hope members of the Asthma Research Council might take up the matter.—I am, etc.,

Sunbury-on-Thames NICHOLAS HAJDU, M.D.Prague.

Biochemistry for Medical Students

SIR,—Dr. C. F. J. Cropper's article, "The Pre-clinical Years" (March 27, p. 389), deserves serious consideration at the present time, and I should like to add something regarding the teaching of biochemistry to medical students.

As Dr. Cropper's article points out, the present tendency is to appoint non-medical biochemists as heads of biochemical departments *in medical schools*. The danger of this practice is that such a department tends to regard its students as potential biochemists and its duty to teach biochemistry as a pure science, for its own sake, so as to turn them into actual biochemists. The fact is that the students intend to become not biochemists but doctors; and if they learn biochemistry it is in order the better to qualify themselves as doctors. Thus to, and for, the medical student biochemistry is largely an applied science and cannot be regarded as a subject by itself; it must be dealt with, in relation to the training of the doctor as a whole. But this relation cannot be fully appreciated by those who have not themselves had the experience of a complete medical training with, in addition, experience in clinical medicine and in the direct application of chemistry to clinical medicine.

I do not suggest that biochemistry should be taught to medical students by those who are doctors only, nor that it should be taught entirely as an applied science. The teacher should be a competent biochemist who is also a doctor, well able to treat the subject as a judicious combination of pure and applied science, capable therefore of dealing with fundamental biochemical principles while stimulating the student's interest by reference to their place in the general scheme of his medical training, and teaching the practical applications of his subject out of a rich fund of his own personal experience.

As a result of the biochemical teaching received in the pre-clinical period the student should feel that the pathological and clinical chemistry taught to him later, in his clinical period, are natural developments and extensions of his earlier pre-clinical studies and not something entirely different; he must be made to feel that what is learnt in the pre-clinical period is not something to be forgotten as soon as he has passed the appropriate examination, but something which he cannot afford to neglect if he is to make a success of his later studies. On this view, the chemistry of the pre-clinical period, and that of the clinical period, if not taught under the direction of the same person should be the subject of close collaboration between the different teachers concerned, to make of the subject a natural co-ordinated whole.

The greatest trial to the hospital biochemist is the resident who causes much unnecessary work, and often misleads himself, by his failure to appreciate the proper bearing of biochemistry on clinical medicine—and the majority of hospital residents appear to fall into this class; certainly the majority of hospital biochemists voice this complaint. If a comprehensive medical service, including full laboratory services, is made available to the whole population, so that every doctor may demand any biochemical test that may occur to him, the state of affairs will become infinitely worse. It is certainly not improved by the attitude of some of the present non-medical teachers of biochemistry whom I have heard refer contemptuously to the applications of chemistry to clinical medicine as "mere clinical chemistry." If they had had experience as hospital biochemists, or were acquainted with such works as Peters and van Slyke's *Quantitative Clinical Chemistry*, they would realize that the subject is worthy of something more than contempt.

This state of affairs appears to show that the biochemical training of the medical student deserves reconsideration. Much of the emphasis must be shifted from purely academic instruction and exercises to the practical application of the subject to medicine. This does not mean that attention should be focused entirely or even mainly on diagnostic chemistry, and such important subjects as the chemistry of nutrition must receive adequate treatment.

In what has already been said there is no desire to minimize the great services rendered by non-medical biochemists to medicine, to agriculture, and to industry, nor to reflect on their capacity to teach and train biochemists. The medical biochemist must keep in close touch with their work, at any rate so far as it concerns medicine, and incorporate its results, where appropriate, into the body of his teaching. He will, of course, undertake research himself, so far as his teaching duties permit.

It might also be added that the really competent biochemist who is also a doctor is not thereby rendered unfit for taking charge of the training of biochemists as well as doctors if his department is charged with this dual function; he is at least as capable of undertaking this double-pronged task as the non-medical biochemist.—I am, etc.,

HOSPITAL BIOCHEMIST.

Foot-and-Mouth Disease in Man

SIR,—I have read with interest the letter of Dr. Kenneth MacLeod (March 6, p. 300) reporting a case in which a diagnosis in man of foot-and-mouth disease was made. I have discussed it with a veterinary friend frequently concerned in the investigation of outbreaks of foot-and-mouth disease, and he makes the following points.

First, the involvement of the hoofs in animals is an essential part of the disease, and in recorded human cases involvement of the areas around the nails is usual. Secondly, if the breath is fetid then the animal cannot be suffering from uncomplicated foot-and-mouth disease. He told of an assistant of his who at one time suffered from what he took to be foot-and-mouth disease, complete with stomatitis and involvement of the nails, in which convalescence was prolonged, and during which the heart was affected. In animals the course of the disease is prolonged, and the crusts round the hoofs seldom separate in less than a month, and are often there for three months.

It would therefore be interesting to hear more about the convalescence of the case reported. A further point is that, in adult humans at any rate, there is a high degree of resistance, and the closest possible contact is necessary to secure infection; and it seems reasonable to doubt whether a child is so much less resistant that merely walking past the farm without obtaining milk therefrom was adequate contact to give rise to infection. Finally, from the description of the case, it seems to me to have been not inconsistent with one of Vincent's angina.—I am, etc.,

I. C. MONRO,
Medical Officer of Health.
Elgin.

Treatment of Fulminating Meningococcal Septicaemia

SIR,—The dramatic response of fulminating meningococcal septicaemia to sulphapyridine administered sufficiently early reported by Dr. J. N. Morrison and Mr. P. W. Houghton (March 20, p. 363) accords with our experience in the following case.

An American soldier aged 34 went to bed on Feb. 14 feeling perfectly well, but woke shortly after midnight with sweating, shivering, and insatiable thirst. He slept fitfully during the remainder of the night. At 6 a.m. he attempted to get up but found his legs would not support him. His thirst remained extreme. He had a slight headache but was mentally clear. Later in the morning he became drowsy, remembers his M.O. commencing to examine him, but nothing subsequent. At 1 p.m. he reached hospital and was seen in consultation with his M.O., Capt. N. Papae. He was flaccid, with a grey, slightly clammy skin, and completely unresponsive to sensory stimuli. He had not vomited but was incontinent of faeces. The temperature was 104.2° F. and the apex beat 156, the radial pulse being uncountable. The trunk and limbs were covered by a diffuse purpuric rash most marked on the abdomen and extensor aspect of the lower limbs, forearms, and hands. There was slight neck rigidity, but Brudzinski's and Kernig's signs were negative. The pupils were of medium size and active to light. The optic disks were normal, and retinal haemorrhages were not seen. The tendon reflexes could be elicited and the plantars were flexor. The heart sounds were pure and the B.P. 68/40. The c.s.f. was under normal pressure but faintly blood-stained. There was no excess of white cells, and meningococci were not found or grown on culture. The white cell count was 10,300 per c.mm., with 89% of polymorphs. Meningococci were not found in direct smears but were grown by blood culture.

Sulphapyridine 2 g. was given intravenously. An hour later recovery was sufficient for the drug to be continued orally, 2 g. being given four-hourly. Two hours after the initial injection he was able to respond rationally to questions and to give some account of his illness. Suprarenal cortical extract was not available, but sodium chloride was administered and the heart supported by adrenaline. By 2 a.m. the temperature had fallen to normal and did not again rise. The pulse rate remained between 120 and 112 for four days, by which time the blood pressure had risen gradually to 95/68; a normal level of 112/70 was reached at the end of the first week. On the second day of the illness the presence of superficial emboli was evidenced by many longitudinal ecchymoses, some several inches in length, chiefly over the extensor aspect of the limbs. The c.s.f. was now heavily blood-stained but sterile, and the urine, which was scanty, contained traces of blood. The white cell count had risen to 42,000 per c.mm. At this time the sulphapyridine content of the blood was 7 mg. %. The spleen did not become palpable at any stage of the illness. The patient made a complete recovery.

By contrast, the possibility of severe meningococcal infection escaping early chemotherapy through mildness of the constitutional reaction was illustrated by the case of another American soldier, who walked from ambulance to receiving ward and complained of sore throat, headache, and backache of 2 days' duration. During chest examination rigidity of the spine was noted, and further investigation showed Brudzinski's and Kernig's signs to be positive, bilateral papilloedema, a slight upper motor neuron weakness of the left face, left nerve deafness, and absent tendon reflexes. The c.s.f. was heavily turbid and under 250 mm. pressure. Numerous meningococci were present. The temperature, however, was normal, and except on one occasion on the seventh day of the illness did not rise above 98.8°. The pulse rate was between 84 and 100. No sulphonamide had been administered previous to admission. He responded to sulphapyridine and made a complete recovery.

H. WOTZILKA, M.D.
Black Notley, Essex.

Changing the *p*H

SIR,—A couple of years ago the *Journal* published a valuable paper which indicated that shock is due to excess of potassium in the blood. As there is no increased intake in these cases the excess of potassium can only come from that which is stored in the cells of the body. Owing to their executive function, disturbance of equilibrium of the nerve cells must be followed by prompt and striking symptoms. The replacement of potassium by injection into the cerebrospinal system, recommended by Stern (*Journal*, Nov. 7, 1942, p. 538), should help greatly to restore equilibrium, the more so since the inorganic potassium used has a higher potential than that in the body with its organic linkages. A similar result is shown in the prompt effect of nascent CO_2 in restoring venous pressure in a system already overloaded with the gas at a lower potential.

The immediate response of the tissues to a disturbance of the Ca/K ratio indicates that the mid-point of unstable equilibrium of the blood and serum has a potential between those of calcium and potassium. Calcium, previously regarded as a powerful divalent base, is placed in the table of negativities well to the acid side of potassium, and the difference in potential between these electrolytes must under abnormal conditions cause stress which will upset the equilibrium in the cell. The difference of the action on protoplasm of these electrolytes is basic: calcium causes shrinkage, potassium swelling; both prevent closure of the body of marine larvae developing in sea-water, the former by contraction, the latter by swelling, and by the formation of vacuoles to such an extent that the tissue disintegrates and loses its power of cohesion.

The very interesting work of György and his school on the quanta-like degradation of the energy of foodstuffs in the body suggests that the subsidiary valencies of atoms, hitherto ignored, have important functions in rearranging atoms within the molecule, and in accepting and furnishing electrons during the different stages of the fermentations. If the individual electron can be traced and its relationships established we should be able to systematize the more potent differences in the potential of electrolytes for practical use. A table giving the critical points of the better-known colloids toward the common electrolytes should be of great use, as this field is practically unexplored.

Some twenty years ago I wrote to the *Journal* suggesting a more detailed examination of the *p*H of malignant tissue. In view of the potent action of calcium on protoplasm it is hard to believe that abnormal adsorption by the malignant cell, giving rise to increased intracellular pressure, a potent cause of proliferation of the cells, would persist unchecked in the presence of abundant calcium ions. A well-boiled suspension of creta praecip. presents no difficulty in preparation or for use in test experiments.

Finally, may I give a practical instance of the effect of changing the *p*H. For about fifty years I tried to dry an ear which had had the ossicles and floor of the epitympanum removed. Addition of 25% of chalk to the boric powder in use worked like a charm. For a number of years now no powder has been needed.—I am, etc.,

RICHARD KERRY.
Montreal.

Intra-uterine Rupture of the Umbilical Cord

SIR,—I was interested in the case of spontaneous intra-uterine rupture of the umbilical cord described by Dr. Kathleen McClintock (April 10, p. 446).

A similar case was seen by me 18 months ago. The patient was a primigravida. The membranes ruptured during the first stage of labour and, soon after, a fairly brisk ante-partum haemorrhage occurred. Bleeding continued for half an hour and then suddenly ceased. It was noted that the patient's general condition remained excellent, but at about the time of cessation of haemorrhage the foetal heart sounds became inaudible. Labour proceeded normally, and some hours later spontaneous delivery occurred. The foetus was stillborn and was remarkable for its extreme pallor. On completion of the third stage it was seen that there was a velamentous insertion of the cord. Air was injected into each of the vessels of the cord in turn, the placenta and cord being immersed in water. The presence of a small rupture was revealed in one of the tributaries of the vein, close to the edge of the placenta in the section of its course not supported by Wharton's jelly. The site of the rupture in the membranes did not suggest that it had been a case of vasa praevia.

In Dr. McClintock's case the foetus apparently died of asphyxia, possibly just before rupture of the cord; but in my case haemorrhage was the cause of death.—I am, etc.,

Leicester. D. R. Cairns.

Venereal Diseases

Sir,—Probably Mr. E. A. Chartres (March 13, p. 331) was deliberately provocative. He makes statements with which I, for one, profoundly disagree. The problem of venereal disease is not an entirely medical affair, and if the moral aspect is ignored it will never be solved. True, education in sex matters has been neglected and recognition of this fact is all to the good, but knowledge without guidance is a poor defence. Science, education, and reason have gone ahead in other directions, reason mainly as a very junior partner, and at the same time true appreciation of moral values has declined. The present struggle in which we are engaged is a telling demonstration of the failure of materialism.

Venereal disease, far from being ordinary, is extraordinary in being completely preventable. It is, in my opinion, unreasonable to sneer at the attitude of the Church, which has consistently emphasized the sanctity of marriage and taught that sexual intercourse outside marriage is wrong. If this teaching were universally followed there would be no venereal disease. It may be that, human nature being what it is, such a standard is not universally attainable, but is it worth while aiming at perfection? Surely we have a clear case where medical science should recognize the practical value of the viewpoint of the Church.—I am, etc.,

S. P. Wilson,
Major, R A M.C.

Sir,—Dr. G. L. Russell (April 3, p. 430) states that direct moral approach was successful. I would be more inclined to suspect that the V.D. specialist he refers to combined his good advice, which acted as sound propaganda, and of course vigorous treatment, and thus achieved that dramatic decline.

Nothing could be better than the close association of doctor and adviser, and more power to those who expend their energies in this direction. In the last war I, as O.C. of a general hospital in the East, talked to the men, warning them as a father to his sons, and I venture to think that my talk was appreciated and had a measure of success. If the parsons wish to take a hand in the good work, let them by all means do so, but few are qualified as men of the world to approach the subject. Morality as taught by the Church has mainly stressed the justice of punishment for lapses, and few of us wish to be kicked when we are down. Therefore, I say, let the medical profession do the teaching and the doctoring, and the schools teach sex hygiene and proper sex behaviour, and not keep this natural information in water-tight compartments.

Dr. Hanschell has not managed to conceal his irritation by introducing irrelevant matter. The second paragraph of his letter is more understandable; it does refer to an opinion held by a section of the profession.—I am, etc.,

E. A. Chartres.

*** This correspondence is now closed.—Ed., *B.M.J.*

The Medical Superintendent

Sir,—May I congratulate you first of all on the timeliness of the article on the medical superintendent (April 10, p. 453). The importance of expert administration of hospitals is being recognized to-day in all quarters.

One cannot but be struck by the immense distance between the liberal position taken up by Dr. Kimber and that which would have been held by the average "medical superintendent" even ten years ago. One wishes also to pay tribute to his effort to be judicial and open-minded. Nevertheless, there is much in his article that ought to be challenged, even if care is taken to avoid mere debating points. Before dealing with the subject proper let me draw attention to the phrase applied to the lay committee, "running the hospital in the interests of those they represent." I do not know if Dr. Kimber visualizes a change in this sphere, but in too many instances such bodies have been representative of political interests. We do not want hospitals to be "run in the interests of" such bodies, and if there were any suspicion that they were politically elected—even if there were a few co-opted members—it is quite unlikely that they would, as Dr. Kimber suggests later, "command the confidence and loyalty of the medical staff."

He refers to medical representation on the committee, but careful reading of his article fails to indicate that this medical representation is to be other than the "medical superintendent" except on special occasions, when "on a resolution by the medical staff committee direct approach by representatives should be allowed." The regular and *de jure* presence of representatives of the medical staff upon the committee, far from being "cumbersome," would facilitate rapid action, as *expert* medical opinion would always be available.

I hope Dr. Kimber will not feel hurt by the use of the word *expert*. Let him consider how hard it is for the specialist to keep himself abreast of his own subject, and then let him ask himself how he, whose specialty is administration, can hope to be sufficiently expert in any other branch to "keep his committee in close touch with current medical practice and progress." Then again, how can he hope to be in a position to "assess the merits of competing departments"? That can only be done by equal discussion among the various experts concerned and a democratic decision arising therefrom. How can he find time and the varied knowledge necessary for the "direct supervision" of the almoner's department in addition to the management of a hospital of perhaps 1,000 beds?

One last point. When Dr. Kimber speaks of no *one* specialist being "responsible for the patient as an individual" and by implication suggests that he is the person to do so, he is striking at the very basis of all sound medicine—the complete responsibility of the clinician for the welfare of his patient. If this principle is not honoured it will not be surprising if confusion results.

No, Sir, being superintendent of a hospital is a whole-time job. The day has gone by when he can be a jack-of-all-trades. I would not prevent a medical man becoming superintendent, but he must be primarily an expert administrator, and as he trains himself for this highly specialized work his medical knowledge will get rapidly out of date. In the smaller units, devoted to such clearly defined entities as infectious or mental diseases or to tuberculosis, he may still find time to devote to clinical work, but in large general hospitals if he attempts to do so he will speedily become a menace to the good of the patient and the smooth working of the staff.—I am, etc.,

Liverpool. John T. Morrison.

Medico-Legal

HOSPITAL GOVERNORS AND MEDICAL AUXILIARIES

Last summer the Court of Appeal dropped a bomb on the rule in Hillyer *v.* St. Bartholomew's Hospital (1909) and blew it into fragments of various sizes. These will continue to travel through the air until the case of Gold *v.* Essex C.C. has been heard by the House of Lords. Their Lordships' judgments will determine the final shape and arrangement of the fragments, and little purpose would therefore be served by exhaustively analysing those of the Court of Appeal at the present stage. A brief statement of them will, however, show how drastically the law governing a hospital's liability for its medical auxiliaries, which had appeared settled for thirty-two years, has been disrupted.

Professional and Administrative Responsibility

The facts were simple, and the Court of Appeal did not disturb the findings of the trial judge, Mr. Justice Tucker.[1] A radiographer employed by the Essex County Council treated a young girl's face with Grenz rays. The dose was prescribed by a dermatologist, but the radiographer had an entirely free hand to carry out the treatment. He negligently omitted to use a ray-proof screen and the girl suffered permanent disfigurement. Through her next friend she sued the county council, but Mr. Justice Tucker held that the rule in Hillyer's case obliged him to say that the Council were not liable for the negligence of their radiographer in the performance of a skilled duty. In Hillyer's case a patient who had been burnt and injured while on the operating table sought to make the hospital governors liable for the alleged negligence of the surgeon and the theatre team. The Court of Appeal unanimously held that the governors were not liable, but of the three judges who composed the court, Farwell, L.J., and Kennedy, L.J., founded themselves on wholly different reasons, and Cozens-Hardy, Master of the Rolls, said he agreed with both of them.

---

[1] *British Medical Journal*, June 20, 1942, p 777.

Lord Justice Farwell said that, although the nurses and other attendants at an operation are ordinarily servants of the hospital, the moment the door of the operating theatre closes behind them they cease for the time to be the servants of the governors, inasmuch as they take their orders from the operating surgeon alone and not from the hospital authorities. The authorities cannot therefore be liable for the negligence of any of them. He added that, even if the hospital authorities were liable, it was not shown that any of the nurses or carriers was responsible for the injury to the patient; the facts were consistent with the surgeon having been the responsible party, and for his negligence the hospital authorities were not liable. He complicated the position by stating in another case two years later[1] that the nurses in Hillyer's case were treated as servants for whom the hospital would be liable, but no case was proved against them.

Lord Justice Kennedy ranged much more widely than the operating theatre. He said that the governors of a public hospital, by their admission of the patient to enjoy in the hospital the gratuitous benefit of its care, undertake that he shall be treated only by experts, whether surgeons, physicians, or nurses, of whose professional competence the governors have taken reasonable care to assure themselves. The governors also undertake to provide fit and proper apparatus for treatment. But he could not infer from the circumstances of the relationship of hospital and patient that the hospital authority makes itself liable in damages if members of its professional staff act negligently towards the patient in some matter of professional care or skill in which the governors neither do nor could properly interfere either by rule or by supervision. He distinguished matters of professional skill from "purely ministerial or administrative duties," such as the summoning of medical aid in cases of emergency and the supply of proper food—duties for the proper performance of which he would be prepared to hold a hospital responsible. This distinction between professional and administrative duties has been regarded as the law of the land by all English courts of first instance until the Court of Appeal's recent decision. The courts were probably influenced by the strong tendency of the Scottish courts to regard medical auxiliaries as independent experts for whose misdoings the hospital was not responsible. Lord Justice Kennedy's principle was restated by Lord Dunedin in 1913 thus: "The managers of a hospital do not go to the public with a profession of themselves operating on or nursing or treating patients. They only hold themselves out as providing an institution where patients will be able to meet with skilled persons who will do these things." In 1932 the Court of Session exonerated a hospital from liability when a patient was burnt by ultra-violet light, and the next year it exonerated another when a nurse was alleged to have been negligent in the administration of medicine. The Canadian courts, on the other hand, have fairly consistently held that a nurse is always the servant of the hospital so as to make it liable for her negligence.

Liability for the Nurse

Lord Greene, Master of the Rolls, said that Hillyer's case has had a remarkable history, and that few cases in the books can have given rise to such a diversity of judicial statement as to the precise nature of the point decided. He could see no authority which prevented the court from examining that case and forming its own opinion as to what it really did decide. As one Lord Justice based his judgment on a narrow ground confined to the necessities of the decision, the other on wide propositions which went far beyond those necessities, and the third member of the court concurred with the reasoning of both, he thought it right to treat the narrower ground as the real reason for the decision. He could find nothing in the judgment of Farwell. L.J., to support the view that the authorities of a hospital are not liable for the negligent act of a nurse in the performance of her general duties as a nurse, whether they require professional skill or are purely administrative or domestic. The principle which the Lord Justice laid down may well extend to cases in which, outside the operating theatre itself, the nurse is acting under the direct instructions of the surgeon or doctor attending the patient. Be that as it might, Lord Greene thought that the true ground on which a hospital escapes liability for the act of a nurse who, in the operating theatre or elsewhere, is acting under the instructions of a surgeon or doctor is not that she ceases to be the servant of the hospital, but that she is not guilty of negligence if she carries out the orders of the surgeon or doctor, however negligent those orders may be. Lord Greene could see no reason on principle why, if a nurse negligently carries out an order, the hospital should not be liable. He found it difficult to understand how the same nurse could be at one moment a servant of the hospital and at another not. Turning to Lord Justice Kennedy's statement in Hillyer's case, that hospital governors are not responsible for the negligence of nurses while performing duties requiring professional skill, he could find no authority to prevent the court from giving its own opinion on the question raised in the present case. When one person owes a duty to another, said Lord Greene, he cannot escape liability because he employs a servant or agent to discharge it on his behalf, whether the obligation involves the use of skill or not. A corporation or a body of trustees can no more escape liability for the breach of an obligation than can an individual. Nor does it make any difference if the obligation is assumed gratuitously.

The relation in which visiting physicians and surgeons stand to the hospital precludes an inference that the hospital accepts responsibility for their negligent acts. The same may be true of house-physicians and house-surgeons, but their case is not relevant to the present inquiry. The position of the nurses also is not strictly relevant, but Lord Greene could not see why the hospital governors do not undertake towards the patient the obligation of nursing him as distinct from the obligation of providing a skilful nurse. Nursing, he thought, is just what the patient is entitled to expect from the institution. He did not distinguish between the position of a hospital and that of a nursing home: a patient entering a nursing home conducted for profit would, he said, be surprised to be told that the home does not undertake to nurse him; his just expectation of a voluntary hospital with the usual nursing staff would surely be the same.

This dictum runs counter to several expressions of opinion, notably by Scottish judges, that a voluntary hospital does not undertake to nurse a patient but only to bring him into contact with persons who will nurse him. The idea, said the Master of the Rolls, that a voluntary hospital undertakes to perform only so-called administrative work appears not merely unworkable in practice but contrary to the plain sense of the position. The position of nurses and of other medical auxiliaries appears to be the same. In the Essex hospital a patient seeking treatment by Grenz rays found a department equipped with suitable apparatus and a whole-time employee engaged for the purpose of giving the treatment. In the circumstances Lord Greene could draw no other inference than that the obligation assumed by the county council was to treat the patient by the hand of the radiographer with the apparatus provided.

Recovery of Fees for Treatment

He added that the nature of the statutory powers under which the council maintain the hospital might well be regarded as conclusive, but that he preferred not to rest his judgment on so narrow a ground. He dealt precisely with the point that was raised recently by a correspondent to the *Journal* who corrected a misstatement made in a note in these columns (June 20, p. 777), that a local authority can recover expenses of maintenance but not of treatment. Actually the Public Health Act, 1936, s. 184 (2, *b*), lays down that the expenses recoverable from a patient by a local authority are to be taken to be "a sum representing the average daily cost per patient of the maintenance of the institution and the staff thereof and the maintenance and treatment of the patient therein." It is clear, therefore, observed the Master of the Rolls, that the council has power to treat patients, and is entitled, and indeed bound in a proper case, to recover the just expense of doing so. If it exercises that power, the obligation which it undertakes is an obligation to treat, and it is liable if the persons it employs to perform the obligation on its behalf act without due care. He could not see how a body invested with such a power and to all appearance exercising it can be said to be assuming no greater obligation than to provide a skilled person and proper appliances.

Responsibility for Permanent Staff

Lord Justice MacKinnon delivered an interesting judgment in which he took the view that Lord Justice Farwell was wrong in holding in Hillyer's case that when the door of the operating theatre closes behind the nurses they cease to be the servants of the hospital. He thought this no more accurate than to say that the captain of a ship ceases to be the servant of the shipowner when he comes under the orders of the commodore of a convoy. He thought the true proposition would be that, though the nurses remain the servants of the hospital in the operating theatre, the hospital will not be liable for their acts if they only do, without personal negligence, what the surgeon directs them to do. Lord Justice Goddard added that Farwell, L.J., seemed to have lost sight of the fact that a nurse, by the terms of her employment, is required to attend on the medical and surgical staff and carry out their directions. She is not like a crane-driver who is lent by his employer to another and placed wholly for the time in the service of that other. He also could not follow the distinction made by Kennedy, L.J., in Hillyer's case between ministerial and professional duties, nor understand why a hospital authority should be exempt if a nurse carelessly gives a patient poison, but should be liable if a cook carelessly puts poison into his food. Hospital managers nowadays, he said, have in their service many specialists—solicitors, accountants, engineers, electricians, and the like He could see no sound reason why they should be responsible for acts of these servants and not for those of nurses. That they are sometimes not liable for a doctor's negligence is merely because he is not their servant. He remarked that he was not considering the position of doctors on the permanent staff: whether the authority would be liable for their negligence would depend on whether there was a contract for service. He could also conceive that a nurse might be regarded as negligent even though she was carrying out the order of a doctor.

---

[1] Smith *v.* Martin & Kingston-on-Hull Corporation (1911), 2 K.B. 775.

Hospital's Complete Liability

These judgments, of course, so far as they go beyond the narrow circumstances of the case—negligence in a radiographer employed by a local authority under the Public Health Act—consist of dicta which, though deserving of great respect and careful scrutiny, are not authoritative. The judgments actually decide that a local authority is responsible for the negligence of its radiographers, and presumably also of its masseuses, chiropodists, or occupational therapists, in the performance of skilled and administrative duties alike. The decision does not in terms extend to the negligence of nurses, but will probably be regarded as doing so. The distinction between skilled and administrative duties of medical auxiliaries and nurses is therefore swept away. By dictum, the court also indicated that (1) a local authority hospital, a voluntary hospital, and a nursing home are all on the same footing in their liability for the negligence of their servants; also that it matters not whether a patient is paying or is being treated free; (2) hospital governors may be liable for the act of a nurse in the operating theatre if by personal negligence she fails to carry out correctly the order of a medical man who has charge of her; (3) hospital governors are liable for the negligence of any of their medical staff with whom they have a contract of service, in the performance of any act within that contract. Unless the views of the Court of Appeal are wholly contradicted by the House of Lords there will almost certainly be a considerable increase in the number of actions for negligence brought against hospital governors, and consequently a drastic extension by decision of their liability for their professional staffs.

Obituary

ANDREW MURDOCH, M.B., C.M.

Dr. Andrew Murdoch, who died at Bexhill-on-Sea on April 10 at the age of 80, was a native of Cumnock, Ayrshire. He received his medical education at the University of Glasgow, where he graduated M.B., C.M. in 1884. He had worked in Bexhill for nearly half a century, where he built up a large practice and remained actively connected with it until his death. For many years he had been the senior practitioner in the town.

Dr. Murdoch (writes a colleague) avoided publicity and disliked the limelight, yet he wielded an influence, both on his fellow-practitioners and his patients, far greater than one might expect even from one of his age and ripe experience. This influence was chiefly due to his personality and character. He was naturally rather retiring, and not given to small talk, but was a man of absolute integrity, honest both with himself and his patients. He expected, from those who put themselves in his care, full co-operation, and, having won their confidence, they were devoted to him and he did not spare himself in their service He was humble in all his ways, but was ever an eager seeker after truth. He retained until the end the enthusiasm of youth and a receptive inquiring mind. He refused to let his mind become blunted by the routine of a busy practice, but was ever ready to investigate and sometimes champion anything, be its origin orthodox or otherwise, that he thought would be for the advancement of medicine and the welfare of mankind. In later years he had studied closely and personally benefited from the technique and teaching of F. Matthias Alexander on constructive conscious control. He realized the medical importance of posture in all its aspects. He read widely both British and foreign authorities bearing on this, and had written a paper embodying his views, which are original and stimulating, as to the mechanism underlying posture. During the past year he had been much encouraged by the sympathetic attention given to his work by those in charge of the Army physical training.

In Bexhill Dr. Murdoch had taken a prominent part in stressing the importance of general practitioners taking an active part in the staffing of the hospital, and when this was opened in 1933 it was with an unrestricted staff, and his influence has been a great help in the smooth working of this arrangement. He was an active member of the B.M.A. for many years, and had filled the positions of chairman of the Hastings Division and president of the Sussex Branch. He leaves a widow and one son, who is serving in North Africa. His only grandson is in the Army in India.

News has been received of the death at Nicosia last year of Dr. **Erroll Aubrey Neff**, Director of Medical Services, Cyprus. He received his medical education at Toronto and became a member of the College of Physicians and Surgeons of Alberta in 1919. He had served in the last war, and after qualifying joined the Colonial Medical Service and later took the Certificate in Public Health of Johns Hopkins University, Baltimore. He was for a time district medical officer at Labasa and then went to Fiji, where for several years he had charge of the leper settlement at Makogai. He was promoted to be D.M.S., Cyprus, in 1934. Dr. Neff's interest in public health was shown in starting the antituberculosis campaign, an intensive campaign against trachoma, and in getting a new general hospital erected at Nicosia and a sanatorium built in the hills. His loss will be greatly felt not only by the members of his Department but also by the general public of Cyprus. He was awarded the C.M.G. in June, 1939.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a quarterly meeting of the Council, held on April 8, with Sir Alfred Webb-Johnson, President, in the chair, the Jacksonian Prize for 1942 was awarded to Mr. E. W. Riches, F.R.C.S., for his essay on "The Methods and Results of Treatment in Cases of Paralysis of the Bladder following Spinal Injury," and a Hunterian Professorship for 1943 was offered to him. The subject for the Jacksonian Prize for 1944 will be "The Causation and Treatment of Delayed Union of Fractures of the Long Bones." The John Hunter Medal and Triennial Prize was awarded to Capt. Graham Weddell, M.B., M.R.C.S, for his research work on the ultimate distribution of the sensory peripheral nerves.

Dr. H. I. Shaheen Bey of the Kasr-el-Aini Hospital, Cairo, and Surg. Capt. W. J. Colborne, surgical specialist, R.N., were elected Fellows under the Charter which permits the Council to elect annually to the Fellowship, without examination, two Members of the College of 20 years' standing.

Mr. A. C. Perry was elected a member of the Court of Examiners for one year from May 13. Mr. Eardley Holland was reappointed representative of the College on the Central Midwives Board.

Diplomas in Child Health were granted, jointly with the Royal College of Physicians of London, to the following candidates:

K. Aterman, Iris M. Cullum, Mary R Davies, Marguerite P. Elman, Martha Klein-Dynski, Margaret E. Matthews, B. U. Meyer, A. Pearlman, Pushpawati M. Shankland, Nuala E. Sheehan, Marjorie Smail, Ruth M. Stevenson, R McL. Todd, I G Wickes, Mair Williams

The Services

CASUALTIES IN THE MEDICAL SERVICES

Missing on Active Service.—Surg. Lieut. I. S. Jacklin, R.N.V.R.

Previously posted Missing in Malaya, now reported Died in Singapore.—Lieut. W F. J. Weston, R.A.M.C.

Died—Capt. W. Darby, R.A.M.C., 1st Class Asst. Surg. F. G. F. Deatker, I.M.D., Major A. L. Kerr, R.A M C., Capt. J. A. C. Tull, S.A.M.C.

Prisoners of War.—Capt. J. B. C. De Lemos, I M.D., Surg Lieut-Cmdr. D. N. Ryalls, R.N.V.R.

Correction.—The obituary notice of Col. W. G. Pridmore (April 10) contained an inaccuracy. It was not he but Capt Whitmore (now Lieut.-Col. A. Whitmore, I M.S., ret.) who made the discovery of a condition somewhat resembling glanders, seen in broken-down morphine and cocaine victims in Rangoon and surrounding districts. It is known as Whitmore's fever or morphine injector's septicaemia.

Medical Notes in Parliament

Nurses Bill

The House of Commons on April 7 went into Committee on the Nurses Bill. Mr. Hutchinson moved to alter the designation "assistant nurses" to "nursing assistants." Miss Horsbrugh said that the nurses on the Nursing Reconstruction Committee had agreed to the term "assistant nurse." This was now being used officially in the Civil Nursing Reserve for those who had had two years' training. The amendment was negatived.

Amendments by Mr. Linstead raised the training and registration of assistant nurses trained in Service institutions. Sir Francis Fremantle said it would be an advantage if the Services were required to consult the General Nursing Council on the subject. Mr. Ernest Brown said he had no complaints about this from the General Nursing Council, which had asked for no amendment of the rules. The amendments were negatived.

Mr. Hammersley raised the admission to the roll of assistant nurses of persons from the Dominions. Miss Horsbrugh asked the House not to accept the amendment because at present there was no standard of assistant nursing in any of the Dominions, nor, so far as she knew, anywhere else. With certain Provinces in the Dominions there was reciprocity for the duly registered nurse. It would not be beyond the power of the General Nursing Council to give the status of assistant nurse to people who had had training and had done some work as nurses. Reciprocity was at present confined to State-registered nurses. The amendment was withdrawn.

On Clause 4 (Fees) Mr. Messer said he could not understand why every year every nurse must pay an annual registration fee. In the medical profession as soon as persons were registered they paid a registration fee and thereafter were on the *Register* until the G.M.C. for some reason removed them. Dr. Haden Guest said that once a nurse's name was on the register it should remain, whether she paid an annual subscription or not, if she was considered fit to carry on nursing duties. An amendment by Mr. Messer was negatived and the clause was approved.

On Clause 6 (Restriction on the Use of Title of Nurse and Assistant Nurse) Miss Horsbrugh said it was clear that tuberculosis nurses should be allowed to call themselves nurses. There might be various categories of persons using the word "nurse" whose claims to do so might have to be examined. The village nurse-midwife might be able to go on the roll of assistant nurses. On Clause 13 (Sister Tutors) Miss Horsbrugh said this marginal note would be changed to "Qualifications for the teaching of nursing." There was nothing in the clause to suggest difference between male and female teachers.

The Bill passed through Committee and its third reading was moved. Mr. Brown remarked that the House passed this Nurses Bill in the same week that a national scale of salaries became effective for the first time. The Bill was then read a third time by the House of Commons. On the same day it secured a first reading in the House of Lords.

Shortage of Nurses

Miss Horsbrugh said on April 7 that, according to latest available information, hospital authorities, both municipal and voluntary, in England and Wales required another 11,341 nurses of all grades to make up present deficiencies. For the shortages in institutions 560 midwives were needed, and another 227 midwives for domiciliary work.

West African Medical Services

On April 7 Sir Francis Fremantle asked the Secretary for the Colonies to consider the possibility of establishing a subordinate medical service in West Africa on the lines of that which had done useful work under the Indian Medical Service. Mr. Stanley said the whole question of medical services in West Africa was under consideration in the Colonial Office. Provision of African medical auxiliaries of all grades, as well as fully qualified medical officers, had already made considerable progress and would be extensively developed as increased training facilities became available.

Interdepartmental Committee on Dentistry

Mr. Ernest Brown announced on April 8 that Mr. Tom Johnston and he, in connexion with the proposals for a comprehensive health service, considered the question of dentistry. The supply of dentists and the arrangements under which their services could be made available must be important factors in determining the extent and form of the provision to be made for the inclusion of dental treatment as a part of a comprehensive health service. Before formulating any proposals he and Mr. Johnston desired the best possible advice on these and other important aspects of the problem and had decided to appoint a committee for that purpose. Lord Teviot had agreed to act as chairman of the committee. Its terms of reference were as follows:

To consider and report upon: (*a*) the progressive stages by which, having regard to the number of practising dentists, provision for an adequate and satisfactory dental service should be made available for the population; (*b*) the measures to be taken to secure an adequate number of entrants to the dental profession; (*c*) existing legislation dealing with the practice of dentistry and the government of the dental profession; (*d*) measures for the encouragement and co-ordination of research into the causation, prevention, and treatment of dental diseases.

Prevention of Dermatitis

Replying to Dr. Morgan on April 8, Major Lloyd George said the subject of dermatitis among miners and the possibility of using barrier substances had been discussed by the Chief Medical Officer of Mines with the factory inspectorate and with the advisory panel on dermatitis set up by Mr. Bevin. Generally speaking, barrier substances were useful only in the case of certain processes. This factor governed their use to a great extent among miners. Certain collieries had already been advised of the existence of these substances with a view to their experimental use. The results would be closely watched by the mines medical officers.

Penicillin

Mr. Ernest Brown said on April 8 that investigations of penicillin, including clinical trials, were being conducted by an expert committee set up by Sir Andrew Duncan, who informed him that owing to the great difficulty of the problems involved this substance was unlikely to be available for general use in the near future, even if the results of the committee's investigations were favourable.

Milk Pasteurization

Mr. Higgs asked on April 18 if Mr. Brown knew that the B.M.A. advocated the pasteurization of tuberculin-tested milk, and if he was satisfied that the process was necessary and desirable. Mr. Brown said he knew of this advocacy. He was advised that, though the risk of contracting tuberculosis from drinking raw tuberculin-tested milk was remote, the danger of its conveying other milk-borne diseases could only be removed by adequate heat treatment.

Manufacture of Contraceptives

In the House of Lords on April 7 the Bishop of St. Albans asked whether the manufacture of contraceptives was officially regarded as of national importance from the point of view of recruitment of labour. His attention had been called to the case of a married woman who had been directed to take up work with a firm, and had discovered that her work was the packing of contraceptives by machine. The daily output was said to be 75 gross or more of cartons each containing 12 contraceptives. This meant an output of over 33,500,000 a year for this firm. The Bishop believed the number of firms so engaged ran into hundreds in this country.

The Earl of Munster, replying for the Government, said no arrangements had been made for recruitment of labour for manufacture of contraceptives. These articles were usually produced by firms mainly engaged in the manufacture of surgical rubber goods and medical supplies. Special arrangements had been made for protection of labour manufacturing medical and surgical supplies which were vital for the use of the armed Forces. No labour was directed into these factories to work part-time or full-time on the manufacture of contraceptives.

Treatment for Venereal Disease.—Mr Parker asserted on April 1 that fees were charged for treatment of venereal diseases at many hospitals and clinics. Mr. Brown said he was not aware of this. It had been made clear to local authorities that treatment of venereal disease at approved centres under their control was to be free. He had no jurisdiction as regards treatment not connected with the public health service of local authorities.

Miners' Medical Service.—Appointments have been made to six of the eight regional posts in the miners' medical services, and five of the medical officers concerned have taken up duty. Appointments have also been made to the two posts at headquarters, but the Deputy Chief Medical Officer will not assume duty for a few weeks.

Free Choice of Doctor.—Sir Adrian Baillie asked the Minister of Health on April 8 by whom the point of view of the public who liked freedom of choice of doctor was represented in the discussions now taking place between the B.M.A. and the officials of his Department. Mr. Ernest Brown replied that discussions were taking place not only with representatives of the medical profession but also with representatives of the voluntary hospitals and of the local authorities The point of view referred to in the question was fully appreciated by all taking part in these discussions.

Medical News

At a Comitia of the Royal College of Physicians of London, held on April 19, Lord Moran was re-elected president.

The spring meeting of the British Orthopaedic Association will be held in Glasgow on Friday, May 14, at the Victoria Infirmary, and on Saturday, May 15, at the Royal Infirmary. On Friday the morning session (9.15 a.m. to 1 p.m.) will be devoted to discussion on spinal cord injuries, followed by a number of short papers. In the afternoon there will be a meeting (largely clinical) at Philipshill Orthopaedic Hospital. On Saturday there will be short papers followed by a clinical demonstration, and at 12 30 p.m. a business meeting of the Association. In the afternoon there will be a joint meeting of the British Orthopaedic Association with the Scottish Orthopaedic Council at Glasgow University.

A "Memorandum on the Control of Head Lice," issued by the Ministry of Health, recounts highly successful experiments in the destruction of head lice and nits with 50% "lethane 384 special" in a white oil. (This preparation was recommended by Dr. J. R. Busvine and Prof. P. A. Buxton in their article in the *Journal* of April 11, 1942, p. 464.) Lethane hair oil does not appear to cause any toxic symptoms, and the Ministry has taken steps to ensure adequate supplies through the ordinary trade channels. Copies of the memorandum can be obtained from the Stationery Office, price 1d. net.

Dr James Fenton, medical officer of health, Royal Borough of Kensington, has been granted the "Smith Award" of the Royal Institute of Public Health and Hygiene.

The Central Midwives Board has re-elected Sir Comyns Berkeley as its chairman for the year ending March 31, 1944.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week there was very little change in the notifications of infectious diseases, with the exception of whooping-cough, for which there were 96 more than in the preceding week. The only county in which there was a large rise was Yorks West Riding with 54 cases, due to the experience of the urban districts.

Total notifications of scarlet fever showed an increase of 28. This was confined to the Midlands, the largest totals being Staffordshire 55, Warwickshire 34, Middlesex 33. In the South there was a decline, the largest being Surrey 49.

There were 11 fewer notifications of pneumonia than in the previous week. The only fluctuation of note within the counties was an increase of 56 in Lancashire, due mainly to the rise in incidence in Liverpool C.B. and Manchester C.B. of 19 and 17 respectively.

Notifications of measles remained almost constant, the 19,568 cases being 7 more than in the previous week. The largest rises were in Hertfordshire 145, Warwickshire 131, Staffordshire 117, Essex 87; and the largest declines were in Middlesex 167, London 163, Derbyshire 154, Suffolk 137, Dorset 91, Sussex 91, Cumberland 89, Yorks West Riding 88.

The 15 cases of typhoid reported during the week constituted the largest weekly total since last September; 7 of the cases were notified in Surrey, Epsom and Ewell M.B.

Notifications of dysentery numbered 17 more than in the previous week, making the highest total for the last two months. No fresh outbreak of any size was recorded during the week, and the only increase of importance was in London, where the number of cases rose from 10 to 18 and involved 11 boroughs.

In *Scotland* a fall of 44 was recorded in the notifications of measles, a rise having been recorded in each of the six preceding weeks. There were declines in the incidence of diphtheria 22 and whooping-cough 10; rises were reported for scarlet fever 20 and primary pneumonia 23.

In *Eire* 9 more cases of typhus were notified in the rural district of Co. Leitrim, where 7 cases were reported last week. There was a large drop in the notifications of whooping-cough, only 15 cases being reported, compared with 75 in the preceding week.

The Week Ending April 10

The notifications in England and Wales during the week included scarlet fever 1,993, whooping-cough 1,954, diphtheria 729, measles 18,056, acute pneumonia 1,290, cerebrospinal fever 92, dysentery 116, paratyphoid 3, typhoid 6. Influenza deaths in the great towns numbered 62.

No. 13

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 3.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

---

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Pneumococcal Vaccine in Pneumonia

Q.—*In treating pneumonia with sulphapyridine or with sulphathiazole is it very advisable also to administer polyvalent pneumococcus vaccine?*

A.—The principal sphere for vaccines is preventive, and their use in treatment, particularly of acute infections, where the stimulus to antibody formation by the infection itself should be at least adequate, is the subject of controversy. In pneumonia the question is complicated by the existence of many serological types of pneumococci which are immunologically distinct. A polyvalent vaccine, if it contains all or many of these, may overcome this objection, but even so only a small fraction of it can exert the effect desired, and the response will be correspondingly small. These are the main theoretical objections to vaccine treatment in pneumonia, and although its practical effect has been reported on favourably we are aware of no controlled study which supports this. In cases requiring such treatment, whether by reason of their severity or because they prove resistant to sulphonamide treatment, it is undoubtedly better, when possible, to type the pneumococcus and administer the corresponding antipneumococcal serum. It should not be forgotten that pneumonia resistant to sulphonamide treatment is often due to bacteria other than pneumococci, and in such cases treatment with a pneumococcus vaccine would naturally be fruitless.

Anterior Pituitary Sex Hormones

Q.—*The hormone of pregnant mare's serum has been referred to as "APL-hormone" on account of its anterior-pituitary-like action. I find that the usually reliable pamphlets of the two biggest drug firms on this subject make a distinction between the action, on the male, of "genuine anterior pituitary sex hormone" and of pregnant mare's serum hormone. They claim for the former an action on interstitial testicular cells ("to be used in infantilism") and for the latter an action on the seminiferous epithelium ("to be used in defective spermatogenesis"). Is there any scientific basis for such a distinction?*

A.—The anterior lobe of the pituitary secretes probably more than one combination of gonadotrophic hormones. Up to the present three separate gonadotrophic functions have been identified. (1) The first, or "follicle-stimulating," brings about maturation of multiple follicles with increase in size and weight of the ovary of the experimental infantile female mouse or rat. This function is concerned with the parenchymatous tissue of the gonad and in the male controls spermatogenesis. The effect is characteristic of extracts of pregnant mare's serum ("P.M.S."), which have therefore been employed in clinical cases of male infertility associated with defective spermatogenesis. (2) The second, or luteinizing, function is concerned with corpus luteum formation, especially of already mature or partially developed follicles in experimental female animals. This effect is produced by injection of pregnancy urine into infantile female mice in the Aschheim-Zondek test, and in segregated doe rabbits in the Friedman reaction. It is due to a gonadotrophin elaborated by chorionic tissue. This is similar to, but not necessarily identical with, "genuine anterior pituitary hormone," and is conveniently referred to as "chorionic gonadotrophin." Its action is upon the interstitial tissue of the gonads, and it therefore stimulates the interstitial cells of the testis, causing them to produce androgen (or male hormone). (3) The third function is a synergic one. Under certain conditions—e.g., in hypophysectomized or very young animals—the effects of extrapituitary gonadotrophins, such as chorionic extracts, fail to develop in the absence of the true pituitary "synergist."

It is more economical to produce a potent gonadotrophin from pregnant mare's serum ("serum gonadotrophin"), which is characteristically follicle-stimulating and spermatogenic, and from human pregnancy urine extract ("chorionic gonadotrophin"), which is luteinizing, stimulates the interstitial cells of the testis, and accelerates retarded descent of the testicles, than to produce a true anterior pituitary lobe gonadotrophin. Furthermore, the gonadotrophic function of true anterior lobe extract varies according to the species from which it is obtained—e.g., ox, horse, sow, etc. Some are predominantly follicle-stimulating, some luteinizing, some synergic. Most of the gonadotrophic extracts on the market which stimulate human testicular interstitial cells are derived from pregnancy urine ("chorionic gonadotrophin") and are not "genuine anterior pituitary extracts."

Magnesium Trisilicate for Peptic Ulcer

Q.—*What knowledge is there of any ill effects due to the prolonged habitual use of magnesium trisilicate in anastomotic ulcers?*

A.—Magnesium trisilicate appears to be the safest of all alkalis or adsorbents for the treatment of peptic ulcer, and apart from an occasional tendency to produce diarrhoea there is no knowledge of ill effects due to its prolonged employment. On theoretical grounds it might be feared that it would absorb the digestive enzymes or the food principles, particularly when a gastro-enterostomy had been performed, but there is no evidence that this really happens.

Vitamin C in Marmalade and Apples

Q.—*With regard to the ascorbic acid value of marmalade, do the cooking and storing of this fruit not cause the vitamin C value to be lost? The same question might well apply to stewed apples. Are apples not better taken raw?*

A.—There is very little destruction of vitamin C in the cooking of marmalade. The lower figure for marmalade (about 25% of the original fruit) is almost entirely due to dilution of the fruit with sugar and water. In fact it is more economical from the point of view of ascorbic acid to turn oranges into marmalade than to eat them raw, because the skin, which contains more vitamin C than the juice, is included in the marmalade, whereas it is discarded when the fruit is eaten raw. About 10% of the vitamin C in marmalade disappears after 6 months' storage, and about 20% after 1 year.

Apples are a very poor source of vitamin C. When they are stewed there is little or no destruction of the vitamin, but again the cooked fruit has a lower vitamin C concentration than the raw because it is diluted with water. The liquor, however, is invariably eaten, so it does not matter whether the apples are eaten raw or stewed.

INCOME TAX

Newcomer to England

R. H. lived in Eire before Feb. 26, 1943; since that date he ceased to be so resident and has been living and working in this country. The facts are sufficiently stated below.

⁂ He is liable to make a declaration, if so requested, to the revenue authorities of both countries for 1942–3. On the facts stated, however, the income will not be enough to produce any material liability.

As regards 1943–4 he will be liable to British (but not to Eire) tax as follows:

Earned Income		
Gross earnings		£520 0 0
Deduct Earned income relief	£52 0 0	
Personal allowance .. .	£80 0 0	
		£132 0 0
		£388 0 0
Tax on £165 at 6s 6d. in the £ ..	£53 12 6	
Tax on £223 at 10s. in the £ . ..	£111 10 0	
£388	£165 2 6	
Less Life assurance relief—£34 at 3s. 6d. in the £	£5 19 0	
		£159 3 6

(If R. H. marries in 1943–4 the personal allowance will be £140 and the tax £129 3s. 6d.)

Property in Eire

Rent £55, less ground rent £10 = £45
Tax at 10s. in the £ = £22 10s. 0d

Assuming that the property forms part of the bank's security for the overdraft the interest on the overdraft can be deducted from the £45.

LETTERS, NOTES, ETC.

Venereal Disease and Alcohol

Dr. G. ORISSA TAYLOR (Reading) writes: By now and rather late the War Office and the Government are both deploring the appalling menace of this disease in the Forces and in civilian life. Whether we feel that broadcast information in matters of sex will help or not, whether ultimate cure of the disease and its prevention are secured or not, the problem is primarily moral. It is foolish to ignore the close association of drink and this disease. We are the custodians of public health, though we may repudiate our responsibility for the morals of the nation. Either the Government does not wish to or dare not intervene in this matter; whichever way it is, this responsibility cannot be ignored without terrible consequences. Years ago Lord Rosebery said: "If the Government doesn't control the liquor traffic, then the liquor traffic will control the Government." The latter is happening now. Hundreds of thousands of the public (many of whom are not total abstainers) protest against this. If beer were rationed and not pushed down people's throats when many urgent necessities of life are scarce and controlled there would be more self-respect, more self-control, and less venereal disease.

Liq. Ferri Perchlor. for Sore Throat

Dr. ROBERT MUNRO (Abergavenny) writes: I have used the following prescription for twenty years in cases of sore throat with gratifying results:

℞ Pot. chlor.	gr. x
Liq. ferri perchlor.	♏ xv
Liq. hydrarg. perchlor.	♏ xx
Liq. strychnin.	♏ ij
Glycerin.	♏ xx
Aq. chlorof.	ad ℥ss

I have also found Mandl's paint or argyrol 20% useful as a local application. In certain cases lozenges of planacrine or potassium chlorate or carbolic acid are helpful; and in others gargles and sprays. However, the above mixture, without the aid of other measures, will generally effect a speedy cure. The sulphonamide preparations are now frequently employed in the treatment of tonsillitis. One of the most useful is a single dose of soluseptasine intravenously, followed by proseptasine orally at four-hourly intervals. It will be interesting to observe if sulphonamide chemotherapy proves more effective than the older methods, especially in view of the untoward reactions that are, unfortunately, liable to follow treatment with sulphanilamide and the related compounds.

Dr. ALEX GAVIN writes: The letter from my friend Mr. J. Cole Marshall (April 10, p. 466) reminds me that I have found that by taking liquor ferri perchlor. in soda water the therapeutic value of the drug appears to be increased, and also makes it far more palatable.

Coarctation of the Aorta as Obstetrical Complication

Dr. C. W. WALKER (Hereford) writes: I was greatly interested in Dr. W. B. Billinghurst's letter (March 6, p. 302) on this subject. His case, in which labour precipitated sudden death, affords additional proof that in these cases compensation that appears to be perfect for ordinary life is likely to break down in parturition, and thus strongly supports my plea for the adoption of Caesarean section in this, fortunately rare, eventuality. I enjoyed Dr. H. S. Gaskell's destructive analyses (April 3, p. 426) of the clinical data supporting the diagnosis of aortic coarctation in my patient (Feb. 13, p. 190). He does not, however, appear to appreciate the diagnostic significance of typical rib-notching (*x*-ray), or of the discrepancy noted between the blood-pressure readings in the proximal and distal circulations (arm and leg readings respectively).

Preparation of Hands for Operation

Dr. S. W. SWINDELLS (Grimsby) writes: This correspondence brings things to my mind which may be of interest and even of use if gloves become more scarce. When I was a resident at the old St. Mary's, then in John Street, Manchester, a method of preparing the hands gave results which were comparatively outstanding in regard to the absence of sequelae. The arms up to the elbows were immersed in a strong (? saturated) solution of permanganate of potash for several minutes; this was followed by a saturated solution of oxalic acid, and this then neutralized by sterile lime water. The feeling of absolute cleanliness which resulted has to be experienced to be believed, and there seemed to be a definite increase in tactile sensation. When I went into general practice gloves were obtainable, and I had little need to use the above—which, by the way, caused no skin irritation even when used several times a day—but I learned something by watching the delightful, fastidious, elderly practitioner whom I had joined. It was an education to see him do a dirty dressing with a pair of forceps in each hand, which he called his "tin fingers" He scoffed when he was told he was practising asepsis and denied the impeachment, declaring that he objected to touching dirty things. Nothing would make him put on a pair of rubber gloves. But he was always gloved when doing dirty gardening jobs. He had started "non-touch" technique

Treatment of Blackwater Fever

Dr. ELTON C. RICHARDSON (London, N.W.1) writes: I have read the article by Lieut.-Col. Felix Smith and Capt. R. Winston Evans on the effect of the *p*H of the blood on haemolysis with special reference to blackwater fever (March 6, p. 279), and noticed they mention that as soon as blackwater fever appears quinine should be stopped. This recalls to my mind the treatment of Dr. R. F. Armour, D.M.O. Portsmouth, Dominica, B.W.I., who in 1935 was treating blackwater successfully with massive doses of quinine by injection. Although I was not a graduate at the time I recall one definite case in which a young boy of 10–12 years, who when first seen had developed "blackwater," was treated by quinine injections, the first two doses being 10 gr. each. The effect of the treatment was observed by the change in the colour of the urine from the dark colour of blackwater to apparently normal (macroscopic) within 18 hours. In adult cases his treatment begins with doses of at least 20 gr. (injection). I feel that this note would be of interest to all who are concerned in the treatment of blackwater, as Dr. Armour, who at that time had 5 successful cases out of 5 to his credit, could not be prevailed upon to publish his findings. His cases were in Europeans and natives.

Allergy to Liver Extract

Dr. B. M. MERRIMAN (London, S.W.1) writes: I was most interested to see the answer given to the question on allergy to liver extract in your column, "Any Questions?" (*Journal*, March 20, p. 370). I have recently investigated the question of allergy to liver extract. As a result several points have clearly emerged: (1) Sensitivity towards liver principle is rarely encountered in comparison with the amount of this material used in practice. (2) Sensitivity is usually acquired during treatment or maintenance. (3) Primary idiosyncrasy is rare, and there is usually either an allergic history or a history of a previous reaction to injections of a similar nature. (4) Once a patient is sensitive to liver protein, changing the brand has little effect. Hence the suggestion raised in the question—"The only preparation which did not produce a reaction of the kind is now unobtainable"—is meaningless. (5) Desensitization can usually be accomplished quite simply; the elaborate series of doses given in your answer is generally unnecessary. The following dosage is usually successful: the administration of 0.2 c.cm. intradermally, followed by 0.5 c.cm. intramuscularly twenty minutes later, and the remainder of the dose intramuscularly after a further twenty minutes. (5) I agree that preliminary skin tests should be made in patients with an allergic history, but suggest in cases showing a strong cutaneous reaction, instead of dilution with saline, simultaneous administration of adrenaline with the liver principle is more satisfactory.

Dr. WM. CORNER (Hove) writes: With reference to the subject of allergy to liver extract (March 20, p. 370) I would recommend the injection of 0.5 c.cm. adrenaline five to ten minutes before the liver injection. This should prevent the development of allergy, and can be continued about six times, which in the ordinary pernicious anaemia case would be five or six months. Thereafter 1/4 gr. to 1/2 gr. ephedrine given one hour before can be substituted cautiously for another six months. Thereafter it probably can be left off, as there seems a natural tendency for sensitivity gradually to clear up. In my experience minor degrees of allergy, such as urticaria, flushing, and tightness of the chest, are common even with the concentrated liver extracts now in use (dose 1 to 2 c.cm.). For these cases ephedrine as directed above usually prevents their development next time. My worst example was the onset of severe acute asthma after the first injection in a newly diagnosed pernicious anaemia case. Adrenaline soon helped to allay the more distressing symptoms Further injections of adrenaline preceding the liver as above prevented any more asthma and proved invaluable in allowing toleration during the intensive early treatment. I may say that most of my liver injections are given at the patients' houses. I would not give adrenaline and liver at my house as adrenaline makes most patients feel shaky.

The Cotton-wool Sandwich

MISS ISOBEL W. BURTON, M.R.C.V.S., writes from the Department of Animal Pathology, Glasgow Veterinary College: Having read Dr. Richard Fawcitt's article (March 20, p. 352) on the use of the cotton-wool sandwich in cases of sharp-pointed foreign bodies in the intestinal tract, I thought it might be of interest to your readers to know of a modification of this method which has been in use in the veterinary profession for some time. Dogs and cats often swallow pins or needles. Usually these are found with the points embedded in the walls of the mouth or pharynx, but sometimes they reach the stomach. In these cases we give the animal twenty to thirty small pellets of tightly rolled cotton-wool, lubricated with lard or vaseline. This is followed in about an hour by a dose of liquid paraffin. The pins or needles are delivered in due course, neatly wrapped up in the centre of a roll of cotton-wool. This treatment has saved many patients from the surgeon's knife.

THE INVESTIGATION OF HAEMOLYTIC TRANSFUSION REACTIONS*

BY

P. L. MOLLISON, M.B., M.R.C.P.

A haemolytic transfusion reaction may be defined as the occurrence of an abnormal destruction of the red cells of either the donor or the recipient immediately after transfusion. Following a normal compatible transfusion of fresh blood the donor's erythrocytes are destroyed only at a slow rate, approximately 1% of the total being eliminated each day; since this is (presumably) the rate of destruction of the recipient's own erythrocytes no signs of increased blood destruction are observed. When incompatible blood or blood that has been stored for an excessive length of time is transfused, however, the donor's erythrocytes are rapidly destroyed and signs of increased red cell destruction develop. Destruction of some of the recipient's *own* red cells may follow the transfusion of blood the plasma of which contains high-titre incompatible agglutinins.

When transfusions are given to persons affected with certain varieties of haemolytic anaemia the signs of haemolysis may temporarily become more pronounced. Such reactions may not be due to one of the causes already considered, and may be listed as rare varieties of haemolytic transfusion reactions.

Haemolytic reactions may be mimicked by the injection of haemolysed blood. This, by the above definition, cannot be considered as a true haemolytic reaction, since the destruction of the donor's erythrocytes precedes transfusion. Nevertheless, the signs produced may be indistinguishable from those of true haemolytic reactions. These various types of haemolytic reaction may be indistinguishable clinically. Each may give rise to jaundice, with or without haemoglobinuria, and each, if fatal, may produce the same post-mortem appearances. On the other hand, each variety may pass unnoticed unless special tests are applied. The purpose of this report is to discuss the pathological features of each type and to describe methods of differential diagnosis.

The establishment of the diagnosis falls conveniently into two parts: (1) the demonstration of the occurrence of increased blood destruction; and (2) the demonstration of the cause of the increased destruction.

The Signs of Increased Blood Destruction

The signs produced by increased blood destruction vary according to whether destruction is predominantly intravascular or extravascular (intracellular).

Intravascular Destruction.—Intravascular destruction results in the liberation of haemoglobin into the plasma. Knowledge of the rate of removal of free haemoglobin from the blood stream has been chiefly derived from experiments in which haemoglobin solutions have been injected intravenously into human subjects. The rate of elimination varies with the initial concentration, being more rapid at high concentrations. For instance, when the initial plasma level is approximately 200 to 300 mg. per 100 c.cm. 50% or more may be removed in three hours (Ottenberg and Fox, 1938), although the plasma may not be entirely cleared for from 8 to 12 hours (Ottenberg and Fox, 1938; Gilligan *et al.*, 1941). When the initial plasma level is only 40 to 60 mg. per 100 c.cm. the plasma may not be cleared for 5 hours.

Haemoglobin liberated intravascularly may be dealt with in three different ways (Fairley, 1940). (1) It may be absorbed by the reticulo-endothelial system and converted to bilirubin, which is then discharged into the blood stream and excreted by the liver. This is probably the only mechanism brought into play when intravascular haemolysis is slight. (2) When intravascular haemolysis is of greater degree part of the haemoglobin is broken down intravascularly and haematin is liberated; this combines with serum albumin to form methaemalbumin, a pigment which may be recognized by spectroscopical examination or, when it is present in only small amounts, by Schumm's test (Fairley, 1940). The rapid intravenous injection of 14 g. or more of haemoglobin (equivalent to the rapid intravascular breakdown of 100 c.cm. of blood) will lead to the formation of sufficient methaemalbumin to produce a positive Schumm reaction, but the rapid intravascular breakdown of two to three times this amount is necessary to produce enough methaemalbumin to be recognized spectroscopically. Methaemalbumin may be detected in the plasma 5 hours after the intravenous injection of haemoglobin, and then persists for 24 hours or more (above data from Fairley, 1940). (3) Some haemoglobin is excreted by the kidney, but only when the concentration of haemoglobin in the plasma exceeds approximately 135 to 180 mg. per 100 c.cm. (Gilligan *et al.*). This concentration may be reached after the rapid intravascular breakdown of approximately 60 c.cm. of blood. Patients who are already passing albumin in the urine may excrete haemoglobin at a lower threshold (Gilligan *et al.*). Once haemoglobinuria has begun it may continue when the plasma haemoglobin level has fallen far below the initial threshold, so that haemoglobinuria may persist for 24 hours or more after transfusion.

When the urine is alkaline the majority of the haemoglobin will be present in the form of oxyhaemoglobin and the urine will be red in colour. If the urine is neutral or acid, however, methaemoglobin will be formed and the colour will be brown or black. Moreover, acid haematin will be precipitated in the kidney tubules, and small casts of this substance will be found in the urine. The latter may persist for several days after transfusion.

Haemoglobinuria is always accompanied by albuminuria (Gilligan *et al.*), and when haemoglobinuria follows an incompatible transfusion it may also be accompanied by glycosuria, as shown in animal experiments by Ottenberg and Thalhimer (1915) and as exemplified by Case 6 below.

Following intravascular haemolysis, some degree of renal failure may occur, with oliguria and a progressive increase in the blood urea concentration. This renal insufficiency is thought by some authorities to be due to blockage of the renal tubules with acid haematin, a relatively insoluble compound of haemoglobin which is formed in acid urine. This theory was originally based on the observations of Baker and Dodds (1925), who showed that in rabbits renal failure after the injection of haemoglobin solutions could be prevented by alkalinizing the urine. The theory has been challenged by De Navasquez (1940), who believes the anuria is the result of a decrease in the rate of blood flow through the glomeruli. DeGowin *et al.* (1938)

---

* A report to the Medical Research Council from the S.W. London Blood Supply Depot.

have stated their belief that, in man, blockage of the tubules is insufficient in many cases to account for the degree of renal failure, and they believe that damage to the tubules by some "nephrotoxic factor" may be responsible.

When renal damage occurs signs of uraemia may not be apparent until at least the second or third day after transfusion, and meanwhile the recipient may appear well. Thereafter a critical phase occurs, usually between the sixth and twelfth days (Bordley, 1931), in which the patient may become comatose and die or else start passing large quantities of urine and recover.

Extravascular Destruction.—The extravascular destruction of red cells results in the production of bilirubin. The degree of bilirubinaemia depends upon the rate of blood destruction and also upon the efficiency of the liver in removing bilirubin from the blood stream.

Signs Common to Blood Destruction, whatever the Mechanism

When, as the result of intravascular or extravascular destruction, the serum bilirubin concentration exceeds 4 mg. per 100 c.cm. (approximately) the recipient becomes jaundiced. Although the serum bilirubin concentration rises rapidly after red cell destruction, usually reaching a peak 5 to 6 hours later (Vaughan, 1942), clinical jaundice is unlikely to occur before the end of 12 hours or so, because time is required for staining of the tissues. As mentioned above, the degree of bilirubinaemia depends upon the rate of blood destruction, so that slow blood destruction is less likely to produce jaundice, other factors being equal. It may also be mentioned that the other main factor affecting the onset of jaundice—namely, the adequacy or otherwise of liver function—may be affected by the transfusion of incompatible blood. Following such a transfusion, evidence of liver damage is sometimes apparent at necropsy and may be manifested during life by the development of signs of toxic jaundice after transfusion. For instance, the van den Bergh reaction may become "direct" (see Case 5) and bile pigments may appear in the urine (see Case 6). Normally, once the destruction of the blood is complete the serum bilirubin concentration falls again, and has usually returned to the pre-transfusion level by the end of three days, and jaundice of the patient seldom lasts for more than two or three days after transfusion.

Because of the blood destruction, the increase in haemoglobin concentration expected as a result of transfusion does not occur when there is a haemolytic reaction. Evidence based on haemoglobin estimations before and after transfusion may be misleading, however, because the patient's haemoglobin concentration may be changing at the time of transfusion (due to the nature of the anaemia, for instance) or the patient's blood volume may undergo alteration. For this reason far more reliable evidence may be obtained in the majority of cases by estimating the survival of the transfused cells by the differential agglutination technique (see below).

Apart from the signs of increased blood destruction, the recipient may show signs of constitutional disturbance and complain of symptoms. For instance, a rise in temperature with or without a rigor is common and the transfusion of incompatible blood may be followed by particular symptoms, which are referred to below. It is important to realize, however, that a haemolytic transfusion reaction may occur without giving rise to any symptoms; and, conversely, it must be emphasized that in the majority of cases the occurrence of a rigor following transfusion does not indicate blood destruction.

Although it is possible to make a theoretical distinction between extravascular and intravascular destruction it is doubtful whether the distinction is a valid one. It may be that destruction is always intravascular, but that when it occurs slowly the free haemoglobin in the plasma never reaches a detectable concentration because it is rapidly absorbed by the reticulo-endothelial system, probably at the site of liberation. That this is so is suggested by the observation that in mild haemolytic anaemias no free haemoglobin can be detected in the plasma as a rule, although in an exacerbation haemoglobinaemia and haemoglobinuria may be noted. It is doubtful whether this represents a change in the mode of destruction, and it seems more likely that it merely indicates an increase in the rate of destruction.

In describing the signs characteristic of various types of haemolytic reactions it should be borne in mind, therefore, that when the signs of extravascular destruction occur the inference is probably simply that destruction has taken place at a slower rate than when the signs of intravascular destruction are noted. There are, however, other features of the various types of haemolytic reaction which are of some assistance in arriving at a correct diagnosis, and these different types will therefore be described.

Destruction of Incompatible Blood

Incompatible red cells may be either agglutinated or haemolysed by the recipient's plasma *in vitro*. Only about 30% of sera will haemolyse as well as agglutinate cells containing the corresponding agglutinogen (Wiener, 1939), but it is important to realize that even when only agglutination occurs *in vitro* intravascular haemolysis may occur *in vivo*. For instance, when Rh-positive blood is transfused to a recipient whose serum contains anti-Rh agglutinins severe intravascular haemolysis may follow (see Case 6, below, and cases described by Wiener and Peters, 1940), although haemolysis never occurs *in vitro* when Rh-positive cells are incubated with sera containing anti-Rh antibodies. The chief factors affecting the mode of destruction would appear to be the titre of the incompatible agglutinins in the recipient's plasma and the rate of transfusion.

In practice intravascular haemolysis is common after incompatible transfusions, although not invariable (see Case 5, for instance). When intravascular haemolysis occurs it is often followed by some degree of renal failure.

After the transfusion of incompatible blood, clumps of agglutinated donor cells may be found in blood samples withdrawn from the recipient. These agglutinates may persist for at least 48 hours after transfusion (as in Case 4), although they may not be detectable in a sample taken immediately after transfusion (as in Case 5). It may be added that whenever there are preformed agglutinins incompatible with the donor blood—that is to say, when the anti-A or anti-B agglutinins are involved or when atypical incompatible agglutinins (usually anti-Rh) are present in the recipient's plasma at the time of transfusion (as a result of previous stimulation by pregnancies or transfusions)—the majority of the donor cells are usually eliminated within a few hours of transfusion. In such cases the agglutinins in the recipient's serum undergo characteristic changes in titre (Rø, 1937; Wiener *et al.*, 1941; Mollison and Young, 1941). There is usually an initial reduction in titre, lasting for one to two days after transfusion, which is probably due to absorption by the incompatible erythrocytes. Then there is a rapid increase, which usually reaches its peak 10 to 20 days after transfusion. Observation of these changes may present valuable evidence, particularly when the donor cannot be traced. When the recipient's plasma does not actually contain incompatible agglutinins but there is potential incompatibility, as when Rh-positive blood is transfused to an Rh-negative recipient, the rate of elimination is variable. If the recipient fails to react to the stimulus of the foreign agglutinogen contained in the donor blood the latter may survive perfectly normally in the recipient. Even after a first transfusion, however, in a person not previously immunized, the recipient may respond by producing anti-Rh agglutinins (although slowly), so that the total survival of the donor cells is reduced from the normal 100 to 120 days to about 60 days (Dacie and Mollison, 1943). In such a case it is of course impossible to detect signs of increased pigment metabolism, and the only evidence of increased blood destruction is the diminished survival time of the transfused cells. In cases in which the recipient has been sensitized by previous transfusions of Rh-positive blood he may respond to a further transfusion by a rapid production of anti-Rh agglutinins and the rapid elimination of the donor cells (i.e., within five to seven days of transfusion). In such a case an increase in serum bilirubin may be detected and the response to transfusion from the point of view of increase in haemoglobin concentration is disappointing (see Wiener, 1941, and Case 1 described by Boorman, Dodd, and Mollison, 1942). Although any case in which the survival of the donor cells is diminished may be considered to be an instance of a haemolytic reaction, the term is in practice restricted to those cases in which destruction starts during transfusion. The term "inapparent haemolysis" has been applied by Wiener to cases in which destruction occurs more slowly after transfusion.

Immediately after the start of a transfusion of incompatible blood the patient may complain of severe lumbar pain (see Cases 1, 2, and 3, for instance), together with various other symptoms, such as burning of the face, tightness of the chest, etc.; some degree of collapse followed by a rigor is common. These symptoms may be delayed, however (see Cases 5 and 6), or abolished by morphine (see Case 3), or may be entirely absent (Case 4). Conversely, they may be produced by the transfusion of apparently compatible serum. One has the impression that the sequelae of the transfusion of incompatible blood are less severe now than formerly, and, if true, this may be due to the increasing tendency to administer blood at a drip rate (apart from cases of acute haemorrhage and "shock"), compared with the more rapid rate that used to be adopted.

Destruction of Stored Blood

(Data from Mollison and Young, 1942)

The rate of destruction of the erythrocytes of stored blood in the circulation of a normal recipient after transfusion depends mainly upon their previous length of storage, the preservative solution used, and the temperature of storage. The erythrocytes of blood stored with a citrate–glucose diluent (M.R.C. War Memorandum No. 1; 1940) at 5° C. for periods up to 10 days or so survive very well in the recipient's circulation, only a very small proportion being broken down during the 24 hours following transfusion and the total survival time being for all practical purposes indistinguishable from that of fresh blood. The increase in serum bilirubin concentration in the recipient's plasma after such a transfusion seldom exceeds 1 mg. per 100 c.cm. Even when the period of storage in this diluent reaches 21 days only about one-fifth of the erythrocytes are destroyed during the 24 hours after transfusion, and the increase in serum bilirubin concentration is unlikely to exceed 2 mg. per 100 c.cm. in our experience, although it should be noted that greater increases were found by Vaughan (1942). The transfusion of blood stored for 21 days in citrate–glucose mixtures is not followed by haemoglobinaemia, and, as Vaughan has shown, methaemalbuminaemia does not occur. Thus, following the transfusion of blood previously stored for 21 days or less with the preservative solution which is in general use, the only signs of increased blood destruction will be the small increase in serum bilirubin (only to be detected by the taking of a venous sample within a few hours after transfusion) and a slightly diminished survival of the donor cells; and the response should be scarcely less satisfactory even from the point of view of the increase in haemoglobin concentration than when fresh blood is used.

The erythrocytes of blood stored in a simple solution of sodium citrate, however, survive far less well in the recipient's circulation than the erythrocytes of blood stored for a similar period in a solution to which glucose has been added. For instance, the erythrocytes of blood stored for, say, 17 days in a simple sodium citrate solution are almost completely eliminated from the recipient's circulation within 24 hours of transfusion. A part of this destruction occurs instantaneously, owing to the rupture of the most fragile cells in the recipient's plasma, although the majority of the cells are not destroyed in this way. The haemoglobinaemia produced by this intravascular destruction is reinforced by the amount of free haemoglobin present in the plasma of the transfused blood, since blood stored with sodium citrate alone haemolyses far more rapidly than blood stored in solutions containing glucose (Rous and Turner, 1916). For instance, blood stored in sodium citrate is about one-tenth haemolysed by the end of 21 days, whereas blood stored for a similar period in citrate–glucose is only about 1% haemolysed. Thus the use of blood stored in a simple citrate solution for 17 days or more is very likely to produce haemoglobinuria and jaundice in the recipient. It may be mentioned that some of the prejudice that still exists against the use of stored blood dates from the early days of the present war, when glucose was not added to blood during storage.

Blood haemolyses more rapidly at room temperature than at 5° C., and it is almost certain that the power of the intact erythrocytes to survive in the recipient's circulation is adversely affected by prolonged exposure to room temperature. It is, however, only of academic interest to separate the effects of the injection of free haemoglobin from the effects of the more rapid destruction of the intact erythrocytes, and it is simply necessary to realize that blood that is left standing about at room temperature before transfusion may give rise to the signs of blood destruction when it is transfused. It may be added that blood stored in the standard 540-c.cm. bottle does not reach room temperature for approximately five hours after being removed from the refrigerator (Oliver and Young, 1940).

Destruction of Recipient's Red Cells by High-titre Incompatible Agglutinins

Intravascular agglutination and haemolysis, followed by bilirubinaemia, have been produced experimentally by the injection of plasma containing high-titre incompatible agglutinins, but only when these agglutinins were present in exceptionally high titre (Aubert *et al.*, 1942). When group O blood the plasma of which contains very-high-titre agglutinins is transfused to recipients of other groups, and a haemolytic reaction follows, it is of course possible to demonstrate that the donor cells survive normally and that it is the recipient's cells which are destroyed (Aubert *et al.*, unpublished observations).

Haemolytic Reactions in Persons Affected with Haemolytic Anaemias

The transfusion of blood to patients affected with at least one variety of haemolytic anaemia may result in an exacerbation of the haemolytic process for a cause other than one of those already mentioned. As an illustration, in a case of nocturnal haemoglobinuria observed by Dacie and Firth (1943) the transfusion of agglutinin-free plasma resulted in the production of haemoglobinaemia, and the transfusion of a concentrated suspension of red cells brought about a very violent haemolytic reaction which was not due to the destruction of the donor cells, since, in fact, the latter survived normally (Dacie and Mollison, 1943).

Haemolytic Reactions Simulated by the Transfusion of Haemolysed Blood

Blood may become haemolysed by the action of contaminating organisms, by being overheated, or by being stored for excessive periods under unsuitable conditions. Certain bacteria will grow freely in stored blood at refrigerator temperature. These organisms usually cause haemolysis of the blood, so that, apart from the possible toxic effects of the bacteria or their breakdown products, the transfusion of infected blood may be followed by the signs of a haemolytic reaction. The consequences of the transfusion of infected blood may be very serious (as in Case 11). When blood is carelessly heated before transfusion it may become haemolysed—for instance, if it reaches a temperature of approximately 55° C. and is kept at that temperature for more than 10 minutes. Inquiry should always be made, therefore, to find out the method of heating (if any).

As mentioned above, blood may become grossly haemolysed if left for a long time at room temperature. The results of the transfusion of blood that had become haemolysed in this way are illustrated by Case 10 (see below).

Investigation of Haemolytic Reactions

At the outset it may be mentioned that the investigation of transfusion reactions suspected of being haemolytic in nature is greatly facilitated if certain samples are available at the time of investigation. These are: (1) a sample of the donor blood, and (2) a pre-transfusion sample of the recipient's blood. In order that these samples shall be available when they are wanted it is desirable that they should be obtained as a routine and kept for a period of 24 hours after every transfusion. It may prove impracticable to obtain a pre-transfusion sample of blood from the recipient before every transfusion, but it should be made an invariable rule that a sample of the transfusion fluid is kept. This is most easily secured by leaving the dregs in the bottle. The apparatus used may be washed immediately after transfusion, but the bottle itself should be recapped and put on one side, preferably in the refrigerator. In all cases the name of the donor or the serial number of the bottle of transfusion fluid should be recorded on the patient's notes. When there is a detachable label on the bottle this should be fastened to the notes.

When pre-transfusion samples of blood are taken from the recipient as a routine they may be conveniently obtained through the needle used for transfusion if the latter is connected with the apparatus by means of an adaptor. Ideally, a few cubic centimetres of blood should be taken into a plain tube and allowed to clot, and a similar quantity should be taken into a tube containing oxalate. These samples should be kept in a refrigerator and not be discarded until the end of 24 hours after transfusion, when the patient has been seen again and been found to respond favourably to the transfusion. When the patient is seen within 24 hours after a transfusion and a haemolytic reaction is suspected, a large sterile venous sample of blood should be obtained and also a clean sample of urine. If the patient is seen later the same samples should be obtained, although many of the tests set out below will be inapplicable.

Precautions to be Observed in Obtaining the Venous Sample.—A large (20 c.cm.) sterile syringe with a needle of not less than 20 S.W.G. should be used. The syringe and needle should be absolutely dry or else must be rinsed in sterile isotonic saline. Venepuncture must be clean. After venepuncture the needle must be removed from the syringe before the blood is squirted into the sample tubes. The sample should be partitioned between two plain tubes (one sterile) and one tube containing dry oxalate.

The Sample of Urine.—It will be sufficient to obtain a clean sample of urine, unless there is any risk of contamination with blood (in a recently delivered woman, for instance); in such cases a catheter sample must be obtained.

Examination of the Samples

In an obscure case the majority of the following tests may have to be made:

(*a*) *Donor's Blood (from the Transfusion Bottle if Possible).*—(i) A sample should first be withdrawn from the bottle with a sterile pipette and kept in a sterile tube in case bacteriological examination is required. (ii) A mixed sample should next be centrifuged to determine the amount of free haemoglobin in the supernatant plasma. (iii) The blood should be regrouped, testing both cells and plasma; if necessary, the Rh group of the cells should be determined. (iv) The cells should be tested against the recipient's serum, using the pre-transfusion sample of the latter when available. (v) The titre of the agglutinins in the donor's plasma should be estimated if necessary.

(*b*) *The Recipient's Blood (Post-transfusion Sample).*—(i) The sample in the sterile tube should be submitted for bacteriological examination. (ii) The serum from the second clotted sample should be examined by naked eye for the presence of haemoglobin or excess bilirubin. If there is no obvious pinkness the serum should be examined spectroscopically. The amount of bilirubin or the icterus index should be estimated, and Schumm's test for methaemalbumin should be applied. The examination of the pre-transfusion sample, when available, is a valuable control. A small amount of serum should be reserved for serological tests. (iii) The oxalated sample should be divided: one-half should be centrifuged, so that the plasma can be examined for pigments as a check on the examination of the sample of serum; the other half should be kept for serological tests. (iv) *Serological Tests.*—(*a*) A suspension of the recipient's blood should be prepared by adding one drop of blood to approximately 2 c.cm. of isotonic sodium citrate or saline (to make a 2% suspension approximately). This suspension should be examined under the low power of the microscope for the presence of agglutinates. With experience it is possible to recognize the difference between weak diffuse clumping due to auto-agglutination and the presence of small scattered well-formed agglutinates lying in a field of free cells, the latter appearance being due to the presence of clumps of donor cells in the suspension. (*b*) The blood should be regrouped, testing both cells for agglutinogens and serum (the latter from the clotted sample) for agglutinins. If necessary, the Rh group of the cells should be determined and the serum examined for the presence of anti-Rh agglutinins. (*c*) The agglutinins in the serum should be titrated for comparison with the results of titrations carried out on samples obtained later and on the pre-transfusion sample (when available). As explained above, characteristic changes occur after the transfusion of incompatible blood, and if a sample of the donor's blood is not available, or if there is any question of the faulty labelling of a bottle so that the true donor is not known for certain, this investigation may be invaluable. (*d*) If necessary, differential agglutination tests should be carried out.

Note on Methods of Differential Agglutination.—Application of the technique of differential agglutination permits the recognition, in a sample of blood taken from the recipient, of foreign red cells derived from a previous transfusion. The donor cells can be recognized either by being agglutinated by a test serum which does not agglutinate the recipient's cells, or by their failure to be agglutinated by a test serum which completely agglutinates the recipient's cells. For example, when the donor is Rh-positive and the recipient Rh-negative, by testing with an anti-Rh serum the donor's cells (if surviving) can be recognized as discrete clumps lying in a sea of free cells. Alternatively, when the donor belongs to group O and the recipient to group A the recipient's cells can be completely agglutinated with an anti-A serum and the free (donor) cells can then be counted in a haemocytometer. Many further possibilities of differentiation are available if anti-M and anti-N test sera are also used.

Application of the method of differential agglutination is practically essential for the solution of many transfusion problems, but reliable results can only be obtained with considerable experience. For a description of methods see Wiener (1942) and Dacie and Mollison (1943).

(*c*) *Sample of Recipient's Urine.*—The urine should be examined by naked eye and its colour noted; it should then be examined spectroscopically for oxyhaemoglobin and methaemoglobin. If the supernatant fluid contains no pigments a sample should be centrifuged and the deposit examined for the presence of pigment casts. The urine should also be examined for the presence of urobilin (Schlesinger's test). The usual tests for specific gravity and for albumin should be carried out and the reaction determined.

(The concluding part, with case reports and a list of references, will appear in next week's issue)

THREE CASES OF PROLONGED FAECAL FISTULA FOLLOWING OPERATION FOR APPENDICITIS

BY

P. T. CRYMBLE, F.R.C.S.

Professor of Surgery, Queen's University, Belfast

A slight temporary faecal fistula following the removal of a gangrenous or perforated appendix is not an uncommon occurrence, but in our experience it closes naturally in a few weeks. One may look for it in those cases in which the inflammation has spread on to the wall of the caecum, or in which closure of the appendix stump has been unsatisfactory. In the past 15 years three persistent and complete faecal fistulae following appendicectomy operation have been encountered, the duration being one, three, and four and a half years. Once the fistula had become established no motions were passed by the normal route, there was marked incapacity for work, and the social result was appalling.

Case I

The first case was that of a child of 6 who was brought to Queen Street Children's Hospital 15 years ago. The child was wasted, anaemic, in a filthy condition, and had been confined to the house for a year. Its condition did not permit of attendance at school. There was a history of two operations—one for removal of the appendix, with drainage of an abscess; and a second one for the cure of an incisional hernia. It was after this second operation that the faecal fistula appeared.

On examination we found the ileo-caecal valve opening on the surface of the right iliac fossa and discharging squirts of fluid faeces. The entire caecum appeared to be absent, and it was decided that a local closure was impossible. After some building up, the abdomen was opened through the left rectus, and a diversion route established in the following way: terminal ileum divided, and both ends closed; transverse colon divided, and both ends closed; lateral anastomosis between the proximal end of the ileum and the distal end of the transverse colon.

As a result of this severe operation the child had a stormy period of five days, but recovered, and was left with a mucous fistula in place of a faecal fistula. The child returned home, put on weight, recovered strength, and was able to attend school. She attended occasionally at the out-patient department, but one was inclined to postpone the removal of the isolated bowel for some years. However, our hands were forced, as some six months after her diversion operation she walked into the out-patient department with the entire ascending colon prolapsed through the fistula and hanging down under her skirt. She was admitted to hospital, the fistula circumcised, and the terminal ileum, ileo-caecal junction, and ascending colon removed. The operation turned out to be extremely easy, as the bowel had already mobilized itself. A few vessels were ligatured and divided and the isolated bowel was removed. There was no reaction, and the wound healed in one week.

The specimen was mounted, and is in the Queen's University museum. It shows a very atrophic terminal ileum (usually mistaken for an appendix by the students in the final examination), the fistulous opening surrounded by a ring of skin and the ascending colon (Fig. 1).

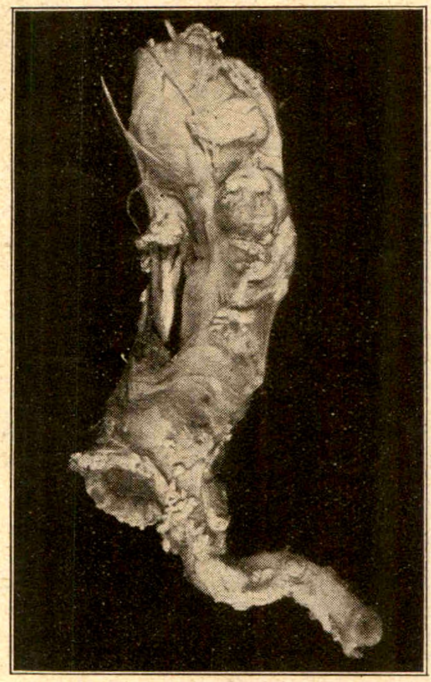

FIG. 1.—The terminal ileum, caecal fistula, and ascending colon removed from a child aged 6 years. Note the atrophic terminal ileum and the almost complete absence of the caecum.

Case II

A young man aged 19 was admitted to the Royal Hospital on Feb. 14, 1937, with a faecal fistula in the right iliac fossa which had been present for three years. A gangrenous appendix had been removed in March, 1934, and a drainage tube had been left in for nine days. The faecal fistula followed the removal of the tube, and persisted. His general condition was quite good, and he was under the impression that a faecal fistula was the usual result of the operation he had undergone. He came to the Royal because he desired to join one of the Services, and had been told that he could not be accepted in his condition. All his motions passed by the fistula, but he kept reasonably clean by packing wool into the opening. Examination of the fistula revealed that it was large bowel, and it was thought that a local closure might succeed.

Technique of Operation.—Fistula circumcised and closed by suturing the skin edges together. Clean towels, gloves, and instruments supplied. Peritoneal cavity opened and caecum separated from the anterior abdominal wall. Narrow-bladed Schoemaker clamp applied to long axis of caecum and the muco-cutaneous tissue distal to the clamp removed, leaving a cuff of bowel wall distal to the clamp. The cuff was then sutured, the clamp removed, and the suture line enfolded.

The wound healed by first intention. The patient had a natural motion on the fifth day, and left hospital on March 3, 1937, with a normal alimentary canal. It was fortunate in this case that there was enough caecum left to permit of closure without in any way obstructing the ileo-caecal valve.

Case III

This case was that of a young unmarried woman aged 19 who had passed nothing by the rectum for four and a half years. In June, 1937, after an operation for appendicitis, a faecal fistula developed, and since then no faeces had ever passed by the rectum. In 1939 three attempts were made to cure the condition, but they were unsuccessful. The first attempt was a lateral anastomosis between two loops of ileum, but this produced no change in the fistula. In the second the two bowel loops distal to the anastomosis were divided and closed, but again with no improvement. (These two operations were presumably done under the impression that the fistula was purely ileal, and involved a portion of bowel some distance from the valvula coli.) The third operation was a direct attack on the fistula, and as it caused complete intestinal obstruction it had to be reopened. She left hospital in fair condition with a complete faecal fistula.

On Jan. 14, 1941, she was admitted to our unit with a history of having four fluid motions daily. She had done no work, but led a fairly normal life. She walked and went to the pictures. There was no emaciation, but she was pale in colour. The whole right iliac fossa showed a skin stippled with small ulcers and areas of white (Figs. 2 and 3). The actual fistula was a complicated arrangement of openings surrounded by a very tender cutaneous margin. The medial half was occupied by the prolapsing end of small bowel (ileum), which discharged no faeces and no gas. The entire index finger could be inserted into it. The lateral half showed two openings, both of which discharged faeces. The upper one could be seen, and it could

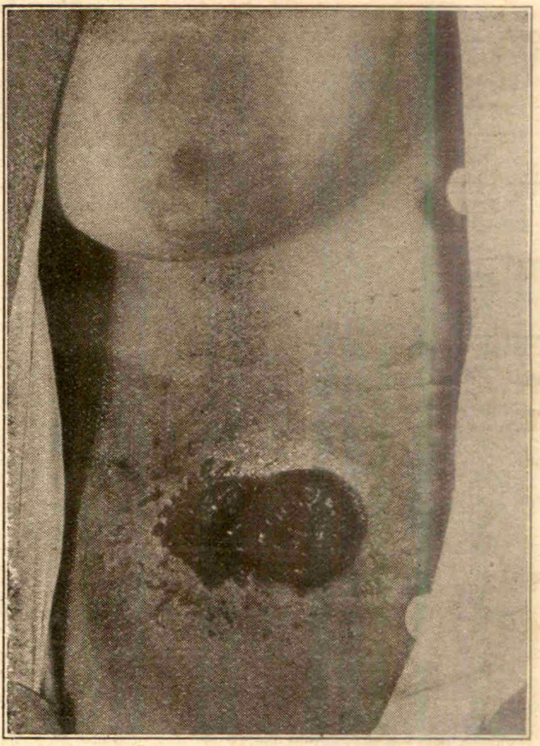

FIG. 2.—The right side of the abdomen in Case III. Note the extensive area of ulcerated skin surrounding the large fistula. Three weeks after the short-circuit operation this skin was entirely healed.

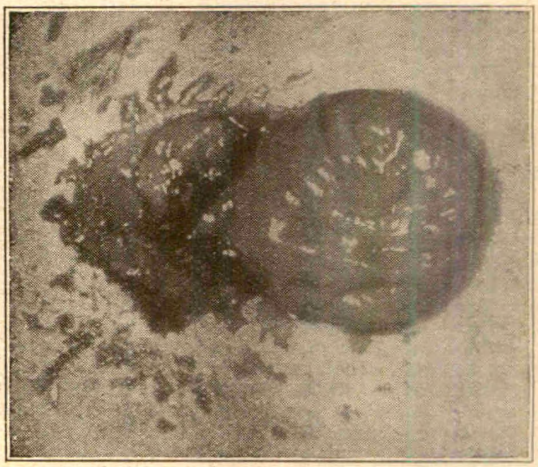

FIG. 3.—An enlarged view of the faecal fistula in Case III. The medial half of the fistula consisted of the prolapsed end of ileum. The lateral half was mainly colonic mucous membrane. Note the ulcerated skin.

be explored with the finger. Its mucous membrane was much paler than the ileal mucous membrane and had the appearance of colonic mucosa. The lower one was too tender to permit examination, and we were uncertain whether it was large or small intestine. Medial to the fistula were two incision scars, one midline and the other right rectal.

Rectal examination revealed a plug of mucus in the ampulla. The patient wore a colostomy belt, which included a large celluloid cup. She was very depressed, had no hope of cure, and showed little enthusiasm for further operative treatment.

Procedure.—The first point was to establish the nature and anatomy of the bowel distal to the fistula. One wanted to be certain that the bowel, which had not been used for four and a half years, was patent, and that the pelvic colon was not involved in the fistula. Olive oil was injected into the rectum and escaped from the two lateral fistulae. Two days later a water enema escaped from the same two fistulae. An opaque enema was then given, and this outlined the colon up to the middle of the ascending colon. It showed a bowel narrow but otherwise normal (Fig. 4). On Jan. 21 the abdomen was opened through a left rectus incision. No adhesions were found in this region, and there was no difficulty in tracing the small bowel from the beginning of the jejunum to that part of the lower ileum which was adherent to the region of the fistula. This portion of the ileum was divided and the two ends closed. The transverse colon was then withdrawn. It was somewhat small and atrophic, and the great omentum was reduced to a short apron about two inches long. The transverse colon was divided to the right of the middle line and the two ends closed. A side-to-side anastomosis was carried out between the proximal ileum and the distal transverse colon.

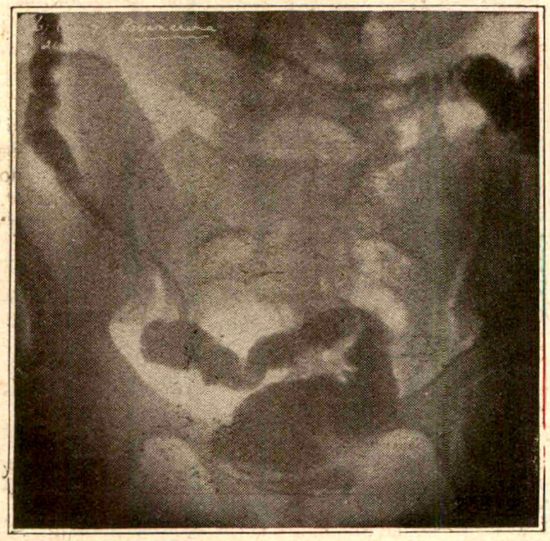

FIG. 4.—Opaque enema of the third case of faecal fistula. The whole colon up to the hepatic flexure is outlined. The pelvic colon has no connexion with the fistula, and the transverse colon is very narrow. This colon had not functioned for four and a half years.

Post-operative Course.—Small quantities of fluid were given by the mouth, and there was constant vomiting for five days. On the 25th she had 53 oz. by mouth and vomited 26 oz. On the 26th she had 38 oz. by mouth and vomited 14 oz. The pulse remained good, and ran between 84 and 100. There was slight evening pyrexia. Constant lower abdominal pain was felt, and the patient remained depressed and irritable.

The fistula was dressed for the first time on the 25th, and was found to be covered with a quantity of faeces. It was thought that this had been extruded from the isolated bowel. The lower abdomen was somewhat distended. On the 27th a little flatus was passed, the pulse and temperature had fallen, the abdominal pain was much less, and the patient for the first time was cheerful. Subsequently the left rectus incision discharged a little faeces for a few days, but it had completely closed by Feb. 5. This was an indication that the ileo-colic anastomosis had leaked. At first there was no control over the rectal discharge, but rapidly control was regained, and by Feb. 7 there was normal control of the sphincters. She left hospital in good condition on Feb. 25. The left rectus incision was healed. The skin around the fistula was free from ulceration, and the fistulous area had contracted and was discharging a little mucus.

Lessons from these Three Cases

1. All were cases of the "late appendix" which required drainage, and the condition would never have arisen if the appendicitis had been diagnosed in the first twenty-four hours.

2. If drainage is necessary, never use anything more rigid than a strip of corrugated rubber or a little piece of gauze. A rigid piece of rubber tubing left in for nine days may quite easily perforate the wall of the caecum.

3. Great care must be exercised in handling inflamed or adherent gut, as it is quite easy to tear or rupture such intestine. If the search for the appendix endangers the gut, it is better to leave the appendix *in situ* and content oneself with drainage.

4. It is remarkable how well a patient may be without the use of the colon. The man aged 19 was in excellent condition, and was well enough to desire to join one of the Services. He was not even depressed with his condition, and kept himself reasonably clean with a large plug of cotton-wool packed into the ascending colon. The woman (Case III) was in fairly good health, and, apart from the fact that she did no work, led a normal life. The surrounding skin in her case was a constant source of trouble.

5. Local closure should only be attempted when the fistula involves the caecum or ascending colon and is some distance away from the valvula coli. For example, the planned caecostomy is the ideal one for local closure.

6. In the presence of multiple openings or where the fistula is close to the valvula coli, one should sacrifice the whole right colon and ileo-caecal region by carrying out a two-stage operation: first a diversion operation, and later a right colectomy.

7. In Case III the essential points were the condition of the colon distal to the fistula and the condition of the small bowel proximal to the fistula. The first point was settled by the injection of olive oil into the rectum (this showed a clear route between the rectum and the fistula) and an opaque enema (which showed non-involvement of the pelvic colon). The second point had to be demonstrated at operation. Had there been numerous adhesions in the left side of the abdomen one might have found it impossible to determine the upper from the lower end of a coil of bowel. Fortunately there were no adhesions, and this problem did not arise.

Classification of Faecal Fistulae

(*a*) Slight temporary fistulae following appendicitis operations.—These require no treatment, and tend to heal in two or three weeks.

(*b*) Fistulae following bowel resection.—These arise at the anastomosis or at the closed bowel end, are usually partial, and close naturally. It is easier for the faeces to pass along the mucous channel than to overcome the fibrotic contraction of the fistula.

(*c*) Injury to bowel during operations on adjacent viscera.—Long-standing gall-bladder or kidney disease may lead to adhesions and weakening of the bowel wall. The removal of the gall-bladder or kidney may leave a weak area of bowel wall unsupported, or the bowel may be injured by the surgeon's manipulations, with the result that a few days after the operation a fistula develops. In one case in which the duodenum was involved death resulted. In a second case the ascending colon gave way after the removal of a very adherent tuberculous right kidney. This fistula closed naturally, but was succeeded by a purulent discharge of some months' duration.

(*d*) The operation of caecostomy.—This can be closed by a local operation when the distal route has been restored.

(*e*) The gross permanent fistula involving the caecal wall, some distance from the valvula coli, following an appendix operation.—This is suitable for local closure as in class *d*.

(*f*) The gross permanent fistula in the immediate neighbourhood of the valvula coli or the fistula with several openings.—This should be treated by a two-stage operation. In stage 1 a short circuit is performed by dividing the ileum (as low down as possible), dividing the transverse colon (closing the distal end), and performing an end-to-side anastomosis between the proximal ileum and the distal transverse colon. This converts the faecal fistula into a mucous fistula. In stage 2 a right colectomy is performed.

Conclusion

A final word of warning with regard to purulent or faecal fistulae in the region of the terminal ileum is that there is a tendency for some of these patients to develop small-bowel obstruction after even slight abdominal operations. They would appear to be balanced on the threshold of obstruction, and are pushed over the edge by any manipulations in that region. It is possible that such catastrophes would be avoided by a preliminary short circuit between the ileum and the transverse colon.

COMPLACENCY IN RESUSCITATION OF THE DROWNED

BY

F. C. EVE, M.D., F.R.C.P.

The manuscript directions for resuscitation by the Schäfer method are in the hands (copyright) of the Royal Life Saving Society, who still regard the method as completely adequate. But knowledge of the very intricate subject of respiration has naturally advanced much since Schäfer's day, and an attitude of complacency will cause us to drift behind other countries. An excellent paper by Surg. Lieut. G. H. Gibbens (1942) has given us a useful jog. He had been bitterly disappointed with Schäfer's method when he used it in his ship on drowning cases—now so urgent a problem. Instead of the normal elastic inspiration on removing pressure to which he was accustomed in normal subjects, the victim's abdomen and thorax "felt like putty." Schäfer's method relies for inspiration on elastic recoil, and this was absent owing to lack of muscular tone. He therefore adapted to ships my rocking method (Eve, 1932), in which a dozen times a minute the patient (lashed to a stretcher) is rocked, face downwards, through a total angle of 60 to 90 degrees on a pivot—provided either by a trestle or by a rope from hammock hooks passed under the middle of the stretcher. On this see-saw the weight of the abdominal contents pushes and pulls the diaphragm alternately up and down by a piston action which is actuated by gravity and does not depend on elastic recoil for inspiration. The ventilation thus secured is quite adequate, and is equal to Schäfer's in the normal subject (Killick and Eve, 1933). The air can be felt, and heard, passing in and out freely; there is no need for voluntary breathing. A manual method is used till rocking has begun. On shore, a builder's two-wheel hand-cart would do well for rocking. Prof. Cordier of Belgium points out that in Scandinavia and Eastern Europe Silvester's method—in spite of its disadvantages—is considered more efficient, especially when tested on the warm cadaver which is toneless. They advance excellent reasons for this preference, which are too lengthy to quote here.

Schäfer's Method

On reading Schäfer's (1907-8) splendid Harvey lecture I see that he started experiments in the dead-house, but found rigor mortis an insuperable difficulty; warm cadavers are not mentioned, nor are drowning cases. Then he proceeded to anaesthetized dogs (drowned) and afterwards to normal humans. Speaking of his method, he says that you should "press gradually for three seconds with both hands close together flat on the back over the loins, the fingers extending over the lower ribs. . . . Of course, on relaxing the pressure the same volume of air must pass in again as the chest resumes its former shape and size."

Unfortunately, this perfectly natural assumption, justified by his experiments on normal people, does not hold good in the nearly drowned, in whom the elastic tone of the respiratory muscles fails progressively. Later, he modified his directions so as to compress the diaphragm only; but with large hands and small loins the ribs cannot always be avoided—neither, in my opinion, can it be an important point when fighting to save a life.

Other Imperfections of Schäfer's Method

The fact is that Schäfer's method has many well-known advantages and may be the best manual method; but it is not a perfect method, and it is deplorable complacency—especially in these days of U boats—not to make every effort to find a better one. We must think not so much of the very numerous successes of Schäfer's method but rather of the distressingly greater number in which it fails, and try to diminish this. A drawback of Schäfer's method is that the weight of the shoulders and upper back opposes inspiration. This, in other countries, has been met by a second operator, who lifts the folded elbows (arms extended high over the head) upwards from the ground during inspiration—thereby greatly improving ventilation and circulation (Hederer). Radiographs have recently shown (Barclay) that in the prone position the diaphragm is pushed up into the full expiratory position, and this second drawback would be increased in the toneless body. This is partly countered (Henderson, 1937) by extending the arms above the head, but both of these methods rely on muscle tone.

The main defect in the nearly drowned is muscular tone, both for circulation and for respiration. It is therefore useless to judge any resuscitation method by its effects on normal persons: the best criterion is the toneless warm cadaver, and I have rocking stretchers at various hospitals to test this aspect.

Tone of the Diaphragm

The diaphragm is the chief and only indispensable muscle of respiration. It achieves inspiration by contracting its high dome into a low dome. In the warm cadaver, as it has lost all tone, the diaphragm is pulled fully up by the elastic contraction of the lungs, and by the pressure of the abdominal contents.

In the semi-final stages of incomplete death, of the three methods of resuscitation Schäfer's will be the first to become impotent with the loss of elasticity (due to tone of the diaphragm), on which he relies for inspiration; Silvester's method will still have some elastic recoil around the ribs to rely on; the piston action of my rocking method should work even more freely as the tone of the diaphragm declines. How swiftly this may happen was shown by H. W. Haggard (U.S.A.), who tried artificial respiration on a man who had just had a fatal heart attack. Ventilation of the lungs was normal at first, but after 10 to 15 minutes it failed completely. The asphyxiated nerve cells of the bulb and spinal cord which maintain the muscles in tone had died, so that the lungs collapsed in the toneless thorax. Henderson (1937) demonstrated another instructive point by measuring the total air respired in a quarter of an hour by various students. Then he tried artificial respiration on them and found the same figure, however hard the operator tried to increase the ventilation of the lungs. The respiratory centre—amazingly sensitive to CO_2—knew exactly how much ventilation was necessary, and by modifying the tone of the diaphragm set the stroke of its piston to give the correct ventilation both in natural and in artificial respiration.

Attempting Better Methods

The trouble with apparatus for the rocking method is that it may not be at hand when needed; but, in a ship, a stretcher which can be rocked could be instantly available, and if resuscitation drill is practised the interval between the victim's lying on the deck and rocking on the stretcher will already have been reduced—with my later gadgets—to 25 seconds. I find, from the officer responsible for first aid in one of the small ships (a mine-sweeper) which carry out many of the rescues from drowning in convoy, that there is no difficulty—as he showed me—in storing, suspending, and rocking a stretcher; he was enthusiastic about it. The short boat journey to the ship is the weak but vital stage. Thwarts and crowding may render the Schäfer method impossible in a boat. So our St. John men at Beverley are trying rocking each other on the four bent forearms of two men (opposite), with their two pairs of legs steadied by a thwart between them. Improvements need working out; e.g., for the two operators to grasp mutually a pair of rings like deck quoits: suggestions are welcome—if tried out. When the method, even in its provisional form, was tried on me in a ship's lifeboat it seemed quite effective. Mr. Akrill, our local first-aid expert, whose help has been invaluable, has to his credit a resuscitation from drowning after 70 minutes of artificial respiration by alternate Schäfer and Silvester—aided by epigastric pushes in expiration, which would help both heart and diaphragm. This seems an excellent plan, for if the current of air at the mouth is not satisfactory by one method you should try another. A local unsuccessful case (by Schäfer only) was that of a short stout woman from whose lungs a pint and a half of water had first been emptied. Such people already have a high diaphragm, and in the prone position her heavy weight pressing on her prominent abdomen would force it higher still. Silvester's method might well have been better for her. Schäfer's method does not always drain away the water as alleged, for in a Hull child recently the water merely bubbled to and fro. Water in moderate amount is quickly absorbed from the lungs into the blood. Drowning cases always suffer from shock, so that in the U.S.A. they are resuscitated in the head-down posture—say 10 degrees—if sloping ground allows. Gibbens points out that this would impede inspiration, but it should help the heart—probably more important.

Other Respiratory Aids

In its very complete review of "breathing machines" the Medical Research Council (1939) states: "For short emergencies we would recommend insufflators of the Oxford or the McKesson type actuated by oxygen pressure and a tilting stretcher based on the Eve principle, which is almost foolproof and needs little attention; its use is a simple extension of instruction in manual methods of artificial respiration. It is therefore particularly valuable in industrial establishments and places where respiratory accidents are frequent." Gibbens (1942) has shown its adaptability to ships. Messrs. Siebe Gorman are (presently) making to my design a simple latticed metal stretcher in which bandaging is nowhere impeded by canvas. If desired it can be rocked, and the rock is reinforced by a jerk—whereby the momentum of the moving viscera and blood columns is valuably enhanced.

The respiratory centre judges the need for deeper respiration by the minutest increase of CO_2 in its blood. Hence inhalation of CO_2, preferably 5 to 8% in O_2, is a potent respiratory stimulant, telling the centre to cause deeper breathing so as to wash out of the lungs the unnatural excess of CO_2. The Novox apparatus is efficient for this purpose, its tube being led via the pivot of the stretcher.

Warmth.—The value of this in shock is well known, and every drowning case is shocked. Heat production is therefore minimal and heat loss very serious, especially in a cold wind and from the evaporation of wet clothes. Hence, besides blankets and hot-water bottles, impervious coverings such as waterproofs are very valuable. Heat loss can only be visualized by the imagination, and even nurses often fail to perceive it. Always we must bear in mind that in resuscitation it is the nerve cells of the respiratory (and spinal) centres which we have to revive with warm circulating blood, oxygenated by moving lungs. With circulation vastly enfeebled the neck and its vital nerve cells may rapidly be chilled. I (Eve, 1900-1) found that the sympathetic nerve cells of the rabbit were killed by a temperature of 50° C., and were paralysed, till re-warmed, by cooling 20° C. below blood heat. High-grade nerve cells should be still more sensitive to cooling, and their blood vessels may be constricted by chill, so that it seems well worth while to apply a rubber hot-water bottle to the cervical spine as soon as Schäfer or rocking has started. A. T. Cholerton writes (March, 1943) from Moscow: "In this winter offensive, even a lightly wounded man, if left lying, dies of frost-shock in 10 to 30 minutes.

Another argument for warmth—to the chest—is that plain muscle, with which the lungs are well supplied, contracts with cold and relaxes with warmth. This is evident in many parts of the body, conspicuously in the scrotum and veins of the hands. Hence the lungs should shrink when chilled externally or internally by cold air and evaporation from redundant ventilation. Warmth should relax the lungs and assist inspiration.

It would be valuable to compare the statistics of successful resuscitation after drowning in cold seas and warm. In Australia there were for ten years no failures in resuscitation on bathing beaches patrolled by the Australian Surf Life-Saving Association. Rescues were prompt and a modified Schäfer's method was employed. But I have seen pictures of these fine young men carrying also a rocking stretcher.

Heart and Circulation

The very important needs of the heart and circulation are not studied enough here. In the U.S.A., Henderson (1937) considers that hypotonia is the essence of shock, and he finds that when, as in drowning, the tone of the muscles is lost the heart fails because it does not get enough blood from veins unsupported by muscle tone. Obviously an empty pump can't work. This theory rings true to me, and I see no inadequacy in it (as he does). For let us substitute—for the heart and artery, veins, and capillaries of the leg of a standing person—a rubber pump and a long vertical rubber U-tube with some cotton-wool in the bottom of it to imitate the capillary resistance. The model will work all right unless the venous return half is replaced by thin-walled tubing, which the blood will distend and in which it will stagnate without reaching the heart. Even if this model is laid horizontally in bed its arterial side will be ill filled (and thus low-pressured) until the "heart" is filled by raising the bed-foot. Similarly, the venous return to the actual heart will fail when the veins and capillaries are deprived of their external support by the muscles universally losing their tone as they do in drowning. Schäfer's method is helpful here because incidentally it squeezes venous blood from the abdomen to the heart. The well-intentioned efforts of first-aiders to stroke venous blood from the limbs appear to me rather fatuous. In this respect the rocking method should be pre-eminent, though the point should by proved by the physiologists; for while gravity will propel the venous blood alternately from the legs and the extended arms towards the heart, the valves in the veins and right heart will prevent the return current. Similarly, the alternating pressures in the chest fill and empty the pulmonary blood into the left heart. The accompanying diagram clarifies the various valuable effects of rocking on the two circulations and the coronaries. Smart but slow rocking (10 to 12 a minute) is probably best for the circulation. As you rock try to visualize the flow of blood in the long veins and arteries.

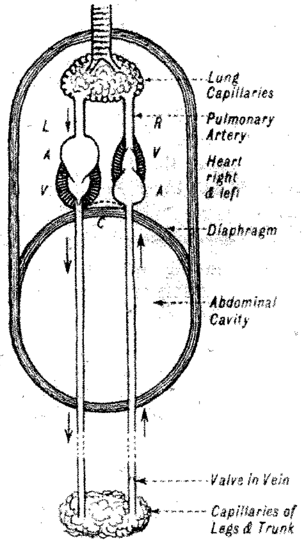

Diagram analysing the effects of rocking on the two circulations

Anaesthetists find (personal letter from Mr. G. H. Colt) that the stopped respiratory centre seldom restarts working unless it is congested; in the rocking head-down posture one can see and feel congestion in the head. This may also restart a stopped heart.

Conclusions

Artificial respiration is a very misleading and therefore, maybe, a life-losing name. For resuscitation is not a simple matter of ventilating the lungs; it is a trinity of *ventilation, circulation,* and *warmth.* Essentially it is an attempt to revive asphyxiated *nerve cells* in the medulla and spinal cord by a circulation of warm blood oxygenated by moving lungs.

Ventilation.—When asphyxiated by failure of respiration or circulation these nerve cells gradually die—usually in a few minutes, but they may remain viable for an hour, rarely more. When they are dead all hope is gone. As they die, the elastic *tone* of the muscles—which they maintain—progressively declines. When the diaphragm has in this way lost all its tone the lungs contract by their own elasticity; they pull the diaphragm right up and become deflated (as in the warm cadaver). At this stage (1) Schäfer's method has become impotent because the elastic recoil of the diaphragm (for inspiration) has gone; (2) Silvester's method will still produce some ventilation owing to elasticity in the thorax independent of its pectoral muscles; (3) the rocking method will effectively shift the flaccid diaphragm up and down independently of tone, and hence should save cases in which loss of tone had gone too far for the Schäfer method to revive.

Circulation.—The heart muscle itself does not die quickly, for after drowning it can be revived by perfusion with oxygenated saline solution—a baby's heart after several hours. The diagram shows how well the head-down tilt perfuses the coronaries. But in shock (hypotonia of muscles) the heart may also fail from mere emptiness because insufficient venous blood gets back to it through veins and capillaries unsupported by tone of muscles. Hence in drowning cases (always shocked) it is important to encourage venous return, as by the compression of abdominal veins which occurs in Schäfer's method or, far more potently, by the rocking method—as already explained. To fill the heart and respiratory centres with blood a head-down slope of about 10 degrees (1 in 6) should be chosen (as on a beach) for manual resuscitation when possible. To fill an empty heart is a quick way to restart it beating. When you tilt steeply to empty out water you incidentally fill the heart and change the coronary blood.

Warmth.—This is indispensable in shock treatment generally—e.g., by hot-water bottles and blankets; also by impervious coverings, to prevent heat loss from evaporation and cold winds. Nerve cells are paralysed by cooling but revive at once on re-warming. With a crippled circulation the indispensable nerve cells in the upper spinal cord will quickly cool and their blood vessels constrict. Hence it may prove very important to warm the back of the neck by a rubber bag early in the resuscitation.

Finally, transcending all else, it is essential to start Schäfer's method instantly: if ventilation (checked at the mouth) is satisfactory, persevere; if not, try Silvester plus expiratory pressure on the upper abdomen, or, better, proceed to rocking if available.

Confronted with so many lamentable failures of Schäfer's method our Naval medical officers seem entirely justified in advising for preference the rocking method, which is now included in BR 25/43, "First Aid in the Royal Navy."

Explanation of the Diagram

Since gravity in rocking affects only the longitudinal components of the blood vessels they may be represented as straight tubes. For clarity, the vessels of the arms (extended on the stretcher handles) and head are omitted: they are similar to the legs. Natural circulation is assumed to have stopped. The piston of this air-pump is formed by the weight of the abdominal viscera (capped by the flaccid diaphragm) sliding up and down. The patient is prone on the rocking stretcher.

When *head-down,* venous blood from the legs and abdomen falls past the right heart into the lung capillaries—reflux prevented by valves in the right heart and leg veins. Veins in the head and extended arms fill. The right heart fills (which may restart it). The aortic valves are banged shut by a pressure of 2 to 3 feet of blood: hence blood is forced into the coronary arteries and joins the stream flowing from the right heart into the lungs (course indicated by the dotted line C).

When *feet-down,* the venous blood which has just been oxygenated in the lungs cannot flow back into the right heart or into the legs (valves closed), but is free to flow past the open aortic valves into the leg capillaries. Blood from head and extended arms refills the right heart.

Thus analysed, slow rocking appears able to aid, or even to maintain unaided, both circulations in the drowned—including the all-important coronary circulation. Silvester's method—unless the epigastrium is compressed—seems to be ineffective on the circulation: Schäfer's method should push some abdominal blood into the lungs but perhaps no further.

My grateful thanks are due to Surg. Lieuts. G. H. Gibbens and D. de Launay, R.N.V.R., for their helpful collaboration and to Prof. R. Hemingway on the physiological side. Also to Mr. Akrill and the Beverley Division of the St. John Ambulance Brigade, and for the use of their hall for experiments.

BLAST INJURY TO THE ABDOMEN BY DEPTH CHARGE

BY

D. DENHAM PINNOCK, M.B., F.R.C.S.
Lieut.-Col., R.A.M.C.

AND

PAUL WOOD, M.D., F.R.C.P.
Lieut.-Col., R.A.M.C.

As little information has been published concerning the effects of blast injury to the abdomen the following cases are recorded in order to supply additional data. Under conditions of active service it is not possible to do justice even to the very scanty literature. However, it can be mentioned that, in Zuckerman's (1940) experiments on animals exposed to air blast, haemorrhagic pulmonary lesions were the chief feature, and that according to Hamilton Bailey (1942) blast injury to the abdomen may be followed by melaena. That author also states that, although laparotomy has been performed with negative findings on several occasions, rupture to the colon has been revealed by timely operation. Breden, d'Abreu, and King (1942) record a number of cases of abdominal blast injury from depth charge, and they refer to papers by Atkins (1940) and by Gordon-Taylor (1940). These records show that persons swimming in the water close enough to an exploding depth charge may suffer blast injury to the abdominal viscera, characterized by shock, haematemesis, melaena, and pyrexia; recovery may take place without surgical intervention; perforation of the gut may sometimes be successfully treated by surgical repair; many of these patients have died before conditions were suitable for careful study or surgical help. Associated blast injury to the lungs is common.

In December a naval vessel was torpedoed and sank rapidly. The crew took to the water and were swimming away from the ship when two depth charges exploded in quick succession. Some who had managed to clamber on to rafts escaped all injury; others who had swum further afield felt the shock but suffered no ill effect; while about 15 felt as if kicked in the stomach or pelvis and were sufficiently injured to be taken to hospital. Of these 15, five were seriously ill and form the subject of this report. The other ten did not appear ill and had no symptoms suggesting serious trauma to internal organs; they recovered uneventfully.

The history given by four of the seriously ill patients was very similar (the fifth was more or less unconscious owing to a head injury received on the ship): they were all swimming in the water with their heads out and supported by life-jackets. Three felt as if kicked in the stomach, the other in the back of the pelvis. After receiving the injury they were still able to swim until they were picked up. They were all seen in hospital within four hours of the event.

Case I

This patient had most of his chest out of the water when the depth charge exploded, for he was trying to lift himself on to a raft. He complained of increasing abdominal pain and had vomited blood, but he developed no pulmonary signs or symptoms.

Examination revealed board-like rigidity with considerable tenderness all over the abdomen, normal lungs, and no fractures or external injuries. His general condition seemed good; the pulse rate was 90 beats a minute and the pulse volume fair. The following day he still seemed fairly well, the haematemesis having stopped and the pulse rate and blood pressure remaining in the region of 90 and 110 respectively, but the board-like rigidity and tenderness of his abdomen had lessened very little. A radiograph of his lungs confirmed the fact that there was no pulmonary blast injury. On the third day it was decided to operate, as his general condition was deteriorating and the abdominal signs were not improving. He was given a pint of plasma before and a second pint during the operation. Laparotomy revealed perforation of the transverse colon with localized peritonitis and two small tears in the peritoneum of the floor of the pelvis. The perforation was repaired and a proximal colostomy tube inserted. The peritoneum was drained.

Rather unexpectedly the patient went steadily downhill, with signs of increasing circulatory collapse, despite repeated infusion of plasma, rectal saline, and fluid by mouth. He died on the fifth day. No necropsy was performed.

Case II

This patient gave the typical history and noted that there was no pain in his chest immediately after the explosion, but that within the next four hours pain around the lower thorax increased steadily. He vomited a good deal of blood and may have coughed up some also.

On examination he was found to be considerably shocked, with a pulse rate of 136 and a small pulse volume. There was board-like rigidity and marked tenderness over the whole of his abdomen, and, although it was thought he had ruptured some viscera, he was too ill for surgical intervention. Repeated infusion of blood plasma and continuous oxygen administration failed to improve his condition, and he died with signs of increasing shock in about 24 hours. No necropsy was performed.

Case III

The history in this case was similar to that of the others: after being withdrawn from the water the man felt increasing pain across the lower thorax and began to cough up blood; there was no haematemesis.

Examination revealed coarse rales over the left lower lobe, with diminished air entry and normal percussion note. There was moderate rigidity of the abdomen, but in less degree than in the previous two cases. The pulse rate was 100 beats a minute, with fair volume. The patient's general appearance was good and he did not look as if he had suffered serious intra-abdominal injury. When seen 24 hours later, however, his condition was worse, shock having increased and signs of injury to the bowel being more evident. There was board-like rigidity of the abdomen with considerable tenderness, but still no haematemesis; haemoptysis was less, but the pulmonary signs were more extensive.

After adequate resuscitation laparotomy was performed and seven perforations of the small intestine were found. The appearance of the gut suggested that many loops of small intestine were severely bruised at the point where they crossed the pelvic brim. There were localized areas of simple bruising, localized areas where bruising had progressed to gangrene, and seven places where a gangrenous section had perforated. In several areas loops of intestine obviously damaged had become stuck together and were not separated; fistulae could well have formed between these adjacent loops. There was widespread peritonitis. Repair was effected by sewing up the perforations and inverting the gangrenous areas that had not yet perforated. The peritoneum was drained, but jejunostomy was not carried out.

The subsequent course was steadily downhill, and was characterized by fever and extending signs of blast-lung, by increasing circulatory collapse—despite almost continuous intravenous infusion of blood and plasma—by complete paralysis of the gut, and by evidence of increasing peritonitis.

After a gallant but hopeless fight the patient died five days after the injury. Necropsy showed extensive haemorrhagic lesions in the lung, with secondary bronchopneumonia, widespread peritonitis, and gross distension of the gut, but no new perforations. A long section of the small intestine was gangrenous, possibly from mesenteric thrombosis following the injury, as no damage to the mesentery was found at the operation.

Case IV

This patient was the only one who received the shock of the explosion in the back of the pelvis, instead of in the stomach. After being dragged out of the water he complained not only of pelvic pain but of increasing raw bilateral lower thoracic pain; he then developed a painful cough with haemoptysis, and each time he coughed it was stated that red blood was forced from the rectum, but the amount was not noted. He tried repeatedly to pass water, but was unsuccessful for four hours, when a catheter was passed with difficulty and normal urine was withdrawn.

On examination he had obvious signs of blast-lung with widespread rales and diminished air entry over the right lower lobe. A radiograph of his chest confirmed the diagnosis and also revealed changes at the left base. In order to avoid further damage the rectum was not examined (what bleeding there was having stopped), nor were there further signs to suggest serious trouble here.

This patient differed from all the others in that his abdomen was soft and not tender. His general condition was good—the pulse rate 90 to 100, with fair volume. He received no special treatment, had no infusion of blood, plasma, or fluid, and made a steady and fairly rapid recovery, so that within 48 hours he was obviously out of danger.

Case V

This patient was unable to give an adequate history owing to the fact that he had received a head injury when the ship was torpedoed and was unconscious in the water when the depth charge exploded. When first seen he was extremely ill, with haemoptysis and physical signs of blast-lung, haematemesis, and board-like rigidity of his abdomen with extreme tenderness. His mental state was confused and drowsy, but there were no localizing signs in the C.N.S. He was badly shocked, and died within 48 hours. He was far too ill to stand surgical intervention. No necropsy was performed.

Commentary

It is not the purpose of this report to discuss the features of blast-lung; but attention is drawn to the fact that in the one patient (Case IV) who had a proved lung lesion the abdomen remained perfectly soft but without gut injury within the peritoneum. Bleeding from the rectum in this case may have been due to damaged haemorrhoids or to small tears in the bowel wall, and it will be remembered that it was this same patient who felt the shock in the back of the pelvis instead of in the abdomen. In contrast, Case I, in which there was a proved gut injury but no symptoms, signs, or radiographic evidence of blast-lung, had marked rigidity of the abdomen. In considering the management of these cases the significance of the abdominal rigidity was questioned, for it has been stated that blast-lung may produce such rigidity. These cases suggest that board-like rigidity of the abdomen should be regarded as evidence of perforation of the gut, and should not readily be put down to blast-lung.

All four patients who had gut injury died, which suggests a worse prognosis than that indicated in the literature described above. When first seen, and for 36 hours afterwards, the condition of two of them was deceptive in that they did not look severely shocked or as ill as one might expect in patients with perforation of the intestine: the facies of moderate well-being was completely unlike the aspect of the common abdominal catastrophe. The rigidity was much more pronounced than we had previously seen in any case of perforation of the intestinal tract; we had only once seen it equalled, and that in a man with rupturing dissecting aneurysm of the abdominal aorta.

That the general appearance was so good misled us to the extent that we were loath to accept perforation as the cause of the rigidity (recollecting what we had read in the Army Medical Bulletin No. 5 of the great rigidity encountered in cases of blast-lung), and the opinion was formed that the condition was due to blast-lung, with probable actual damage to the abdominal muscles. Even 24 hours later, when there was obvious deterioration in the condition of these patients and when operation was decided upon, one of our surgical colleagues remarked that he had not seen a patient with a perforated viscus of so many hours' standing with so good a facial aspect, and could not believe that such a catastrophe had occurred.

It is probable that these patients would have done better with immediate surgical intervention. On the other hand, the lesions found at laparotomy in Case III make it clear that perforation results from gangrene supervening on gross bruising, and that many patches of bruising do not lead to gangrene and perforation, so that too early laparotomy might defeat its purpose if perforation were to occur subsequently. However, the findings point to the necessity for exploration of the abdomen in cases of this type, and in future one would prefer to explore—even in the early hours—and find nothing more than bruising of the viscera, and would be prepared to operate a second time if a later perforation occurred.

INTOLERANCE TO LIVER EXTRACT IN PERNICIOUS ANAEMIA

BY

ELIZABETH DELIKAT, M.D.Bratislava

Assistant Pathologist, the Royal Hospital, Wolverhampton

It is a matter of common experience in clinics devoted to the treatment of pernicious anaemia that a certain small proportion of patients treated with liver by the parenteral route in course of time become "sensitive" to the injections. In such cases treatment may successfully be carried on by the oral route; this method of administration of liver extract is, however, extremely wasteful, and the Ministry of Health has made an Order, dated May 21, 1941, under Regulation 55 of the Defence (General) Regulations, 1939, which lays it down that liver extracts shall not be administered otherwise than by injection. At the suggestion of Dr. S. C. Dyke, Director of the Pathological Department of the Royal Hospital, an inquiry has therefore been undertaken into the possibility of inducing patients who had become sensitive to liver to tolerate their requirement by parenteral injection.

Out of about 200 patients with pernicious anaemia attending the department over the past fifteen years 14 were known to have become intolerant to liver by parenteral injection. None of these gave any previous history of allergic manifestations, but in all cases the symptoms of intolerance were those usually associated with allergic hypersensitivity. These ranged from slight local manifestations at the site of injections, such as redness, induration, and itching, through all gradations up to severe constitutional reactions associated with generalized urticaria, vomiting, failure of vision, and attacks of typical spasmodic asthma. In some cases the symptoms were alarming, and necessitated the detention of the subjects in hospital; in the milder cases they responded readily to ephedrine by mouth, and in the more severe to adrenaline hypodermically. It was found that once sensitization had been established it extended to all brands and types of liver extracts; attempts to carry on treatment with preparations other than those responsible for the sensitization were uniformly unsuccessful. In some cases the allergy was only transient; in others it was persistent and had necessitated a change-over to administration by the oral route. Three cases of this latter type formed the subject of this investigation.

Treatment of Three Cases

Case 1.—Man aged 52. Under treatment for pernicious anaemia since May, 1939. Maintenance dosage, 4 c.cm. of liver extract parenterally every six weeks. In Oct., 1940, after the usual injection he developed generalized urticaria, with puffiness of the face and failure of vision; thereafter he was treated with liver extract orally, 1 oz. daily, until Dec., 1941, when it was decided to attempt desensitization. Intradermal tests with 0.1 c.cm. of two different brands of liver extract gave strongly positive skin reactions. The attempt at desensitization was begun with a dose of 0.1 c.cm. of liver extract, which was tolerated well; increments of 0.1 c.cm. were made at each successive dose, given every second day until a dose of 1 c.cm. was reached; thereafter an increment of 0.2 c.cm. was used. The patient attended every third day, and remained in hospital for two hours after each injection until he could tolerate 3 c.cm. of liver extract in one dose. This dose was increased by 0.5 c.cm. at two-weekly intervals until 4 c.cm. could be given in a single injection. The patient now tolerates this dose every four to five weeks, and on it a normal blood picture is maintained. On some occasions after this injection of 4 c.cm. of liver extract he complains of slight headache and shows some swelling of the forehead; this disappears on giving ephedrine. He is admitted to hospital for two hours for each monthly injection; probably it will be possible to dispense with this precaution in the future. The intradermal tests with liver extract are still strongly positive, though less so than before desensitization.

Case 2.—Woman aged 61. Under treatment for pernicious anaemia since May, 1939. On maintenance dose of 4 c.cm. of liver extract parenterally every two months until 1940. In March, 1940, she collapsed after her injection; the same thing happened again in May, 1940. Treated by liver extract orally, at first 1 oz. and later 2 oz. daily. This dose was not enough to maintain a normal blood picture, and in Sept., 1941, it was decided to attempt desensitization. Somewhat surprisingly, skin tests with liver extract gave negative results. For the next five months she was admitted to hospital for one day every four weeks and received her liver extract parenterally in divided doses, starting with 0.1 c.cm., with increments of 0.1 c.cm. every 20 minutes so long as no reaction occurred; on the occurrence of a reaction time was allowed for the symptoms to subside, when the previous dose was repeated. The reactions consisted of tachycardia, vomiting, and malaise; there were never any dermal manifestations. By Jan., 1942, the patient tolerated a dose of 2 c.cm. of liver extract in two injections of 1 c.cm. at an interval of one hour. At this time the state of the blood was not satisfactory, but an attempt to raise the total dose to 2.5 c.cm. resulted in severe collapse. In March, 1942, owing to the unsatisfactory state of the blood picture she was admitted to hospital. She then received 6 c.cm. of liver extract parenterally in divided doses over two days. After a single dose of 1 c.cm. she developed for the first time generalized urticaria, and intradermal tests with 0.1 c.cm. of liver extract were found to be strongly positive. In spite of this she now tolerated a dose of 0.5 c.cm. of liver extract, and a desensitizing course was started from this level with increments of 0.1 c.cm. daily up to a single dose of 1.5 c.cm. This injection, however, again gave rise to generalized urticaria, and had to be repeated the next day, when it was well tolerated. Desensitization was thereafter continued with increments of only 0.1 c.cm. up to a dose of 2 c.cm., and later of 0.5 c.cm. until 4 c.cm. was tolerated in one dose. A total of 34.5 c.cm. of liver extract was given in 21 days. The patient now receives 4 c.cm. of parenteral liver extract in a single dose every four weeks without disturbance.

Case 3.—Female aged 44. Under treatment for pernicious anaemia since Aug., 1940. Maintenance established on a dose of 2 c.cm. of liver extract parenterally every two months. In May, 1940, after her usual injection, she developed generalized urticaria and collapsed. On three more occasions she developed urticaria after her injection. In Jan., 1942, intradermal tests with 0.1 c.cm. of liver extract were strongly positive. This patient has been unable to spare the time for frequent attendances at the hospital, and in her case no serious attempt at desensitization has therefore been made. She attends every six weeks and receives her requirement of liver extract in divided doses, starting at 0.1 c.cm., with increments of 0.1 c.cm. at intervals of 20 minutes until the first signs of intolerance appear; these in this case are flushing of the face and a feeling of tightness of the throat, and usually appear after a single dose of 0.3 to 0.4 c.cm. She then goes home and returns on the following day, when we have found the injections to be well tolerated. Dosage is started at the level reached on the previous day and proceeds at increments of 0.2 c.cm. at 20-minute intervals. The full requirement of 4 c.cm. for six weeks is usually injected in two days.

In all our cases the symptoms of intolerance to liver injections appeared only after several months or years of parenteral treatment; the interval between the injections was at least six weeks, for the reason that no patients under maintenance treatment in this department receive their injections at shorter periods.

Discussion

In view of the facts there is every reason to suppose that the intolerance is an anaphylactoid phenomenon and due to "allergic" sensitization, the liver acting as an antigen. This is the usually accepted view (Criep, 1938; Jones, 1939). Our experience, using different brands and types of liver extract, would lead us to believe that none are free from bodies capable of this antigenic action. Various methods of desensitization have been suggested: splenic extract (Schlesinger, 1930); histamine (Corelli, 1935); "quotientin," which appears to be an empirical remedy alleged to contain hypophysial, parathyroid, and suprarenal extracts (Lasch, 1936); various preparations of calcium (Lasch, 1936; v. Herff, 1937; Gigante, 1939); liver powder orally in increasing dosage (Diena, 1938); and the parenteral injection of liver extract in divided and increasing dosage (Engel, 1933; Grün, 1933, 1934; Krantz, 1938). This last, in view of known facts as to sensitization and allergy, appears to be rational, and was therefore adopted in this investigation.

That negative skin tests do not exclude intolerance to liver extract is shown by Case 2, in which these were negative 18 months after the onset of symptoms and became positive only during the attempt at desensitization. Two methods may be adopted for the parenteral administration of liver extract to intolerant patients: lasting desensitization can be achieved by a course of liver injections in increasing doses over several weeks; alternatively, the required dose may be given in small injections, preferably over two days. The latter method does not increase the tolerance of the patient to future doses.

Summary

Three cases of pernicious anaemia are described in which the patient had become "sensitive" to the parenteral injection of liver extract.

Skin tests cannot be relied upon to indicate intolerance.

By the use of divided doses of liver extract over a period of several weeks it proved possible to desensitize two patients to the extent that they became able to tolerate their full requirement of liver extract in one injection at monthly intervals. In a third case the required dose is being given in small injections over two days without attempt at permanent desensitization.

My thanks are due to Dr S C. Dyke for access to records and advice, and to Sister Dora Martin for care and supervision of the patients while in the wards.

Medical Memoranda

Irritation of the Urinary Tract by "Doped" Beer

On the afternoon of Oct. 6, 1942, two ratings reported sick on board, one with the clinical features of acute pyelitis and the other with those of acute anterior urethritis. Provisionally these were regarded as infections with *B. coli communis* and the gonococcus respectively, and in both cases treatment with sulphapyridine and alkalis was instituted. There appeared, however, to be something unusual about these cases. First, acute pyelitis is an uncommon condition in young men; and, secondly, the rating with urethritis had a temperature of 102° F, with only a very slight mucous discharge. This pointed to the possibility of some causative factor common to both, and on close questioning it transpired that these two men and a companion had on the previous afternoon visited a brothel when the ship had put into port for a few hours. There they had had some beer, which, though it tasted normal, probably contained an aphrodisiac of the nature of cantharides, which had acted as a violent irritant of the urinary tract. It is known that for business purposes the proprietors of brothels do "dope" their drinks in this way, and naval personnel are advised never to quench their thirst at such places.

The third rating in the party complained of no symptoms whatever, and subsequent microscopical examination of his urine revealed no evidence that he had been affected. The stories of all three, however, combined to make it clear that he had drunk much less beer than his two companions, and that the one with pyelitis had had considerably more than the one with urethritis. There was thus a fairly close correlation between the amount of suspected beer consumed and the severity of the subsequent symptoms.

Case Records

Case 1.—Able Seaman "X," aged 22, reported sick on Oct 6, 1942, complaining of severe pain in the penis at the end of micturition during the past few hours; he was passing water about every half-hour with some urgency. Aching pain was also felt across the loins, spreading down the back of the thighs into the calves. Frontal headache and nausea were present. He had never had a similar attack in the past nor any other urinary trouble. Examination showed: temperature 103° F.; tongue furred; tenderness in both loins and over the pubes; neither kidney palpable. The urine was cloudy, with a naked-eye deposit of pus on being left to stand (Microscopy was not possible until two days later.) Progress was as follows: Oct. 7: Restless the previous night and vomited four times. Morning and evening temperatures 99.2° and 98.4° F. respectively. Frequency becoming less. Oct. 8: Pain now present during whole act of micturition. Nausea and generalized abdominal discomfort. Tender in both renal angles. B.P. 110/80. Urine clear to naked-eye inspection, but many pus cells and an occasional red cell seen on microscopy; no casts or organisms seen. Oct. 9: All symptoms diminished, but back still weak. Developing herpes labialis. Some pus cells and an occasional red cell present in urine. Oct. 14: Return of pain in the back and painful micturition. Temperature up to 101° F. Tender in loins, above Poupart's ligaments, and over pubes. Many more pus cells present in urine. Oct. 22: Patient completely recovered; symptomless; no pus cells visible even in a centrifuged specimen.

Case 2.—Able Seaman "Y," aged 24, reported sick on Oct. 6, 1942, complaining of pain in the penis on micturition during the past few hours; pain worse at the end of the act; a little frequency but no urgency. Intercourse the previous afternoon and five days before. No history of similar trouble or of venereal disease in the past. Examination revealed a temperature of 102° F. and very slight mucous discharge from urethra. (A smear taken before starting treatment with sulphapyridine was subsequently shown to contain a very few pus and epithelial cells only—no gonococci.) Progress was as follows: Oct. 7: Passed water four times the previous night; complaining of nausea and dizziness; temperature normal all day. Oct. 8: Appetite returning; pain during micturition still present; no urethral discharge. Many pus cells seen in urine on microscopy. Oct. 9: Urine contained a few pus cells. Oct. 11: Feeling well; symptomless; only a very occasional pus cell seen in urine.

Comment

One case each of acute pyelitis and acute anterior urethritis are described, both suspected of being due to an aphrodisiac taken in beer consumed at a brothel. Unfortunately there has so far been no opportunity for making further inquiries concerning the nature of the suspected "dope."

Between them these two cases present an interesting study of the symptoms produced by irritation of the urinary tract from renal pelvis to anterior urethra, and it is regretted that, owing to the difficulties of practising medicine on board a destroyer, it was not possible to investigate them in further detail.

Influenzal Meningitis in a Child aged 2 treated with Sulphapyridine: Recovery

The following case is of interest as an example of the successful treatment of influenzal meningitis with sulphapyridine. A similar case has recently been reported by Birch in a child aged 3.

Case History

The patient, a boy aged 2, was admitted to hospital on Dec. 11, 1942, with a week's history of a running nose and general malaise. Two days before admission he had a convulsion and became drowsy, and this was followed in a few hours by the onset of diarrhoea and vomiting, with constant twitching and rolling of the eyes. He had a past history of recurrent otitis media of the right ear, and measles five weeks before admission. He was the youngest of a family of four, the others being healthy.

When first seen he had a temperature of 100.4° and was drowsy and confused, with marked neck stiffness and a positive Kernig's sign. The right ear-drum was pink and opaque; the left one was normal. Lumbar puncture was performed, and the cerebrospinal fluid on the second day of illness was turbid and under increased pressure. It contained 2,740 cells per c mm—85% polymorphs—protein 190 mg. per 100 c cm, and chlorides 755 mg. per 100 c.cm.; sugar was present Sulphapyridine was started, with an initial dose of 1 g. followed by 0.5 g. four-hourly. The following day the child was still vomiting, and an intravenous infusion of 5% glucose in normal saline was given. He was very restless, and the temperature was still raised, but the right drum was no longer injected. The C.S.F. had grown a pure culture of a Gram-negative haemophilic organism, subsequently identified as *H. influenzae* on its requirement of both X and V factors. On the third day the child was very much improved; the temperature had fallen, and the saline infusion was stopped. Sulphapyridine was given in a reduced dose for a further five days, making eight days in all and a total of 17 g. On the tenth day the C.S F. was sterile, and contained only 35 cells per c.mm., of which 80% were lymphocytes.

The temperature continued to fluctuate between 97° and 100° for three weeks, but the child was apparently well and had no physical signs. He was discharged on January 15, 1943, when he had been afebrile for a fortnight.

Reviews

WAR SURGERY

The Principles and Practice of War Surgery. With Special Reference to the Biological Method of Treatment of Wounds and Fractures. By J. Trueta, M.D. (Pp. 391; illustrated. 42s.) London: Hamish Hamilton Medical Books, in conjunction with William Heinemann. 1943.

Osler was wont to remind us that by the historical method alone can many problems in medicine be approached profitably, and the author of this book has made full use of such an approach to the problems relating to the treatment of war wounds. Through the practice of the great master surgeons of the past he traces for us how "the right philosophical basis produced the right technique."

The subtitle to the book is a happy one because its author's methods of treatment, by assisting natural repair as they do, may well be described as biological in character. How often in the past have misdirected surgical efforts retarded rather than assisted recovery! Dr. Trueta traces the surgery of war wounds from earliest times, from the days of early amputation of compound fractures to the beginning of the period of conservatism initiated by James Syme and William Fergusson, who in 1842 wrote: "It is a grand thing when by prescience even the tip of a finger can be saved." The author pays due tribute to his predecessors, including Winnett Orr, who instituted the methods which he has developed and which are here set forth in detail. While remembering that Winnett Orr, and possibly others also, may have been the originators of these methods, we do well to bear in mind an observation of Sydney Smith's, that "it is not the man who first says a thing, but it is he who says it so long, so loudly and so clearly, that he compels men to hear him; it is to him that the credit belongs." This applies very forcibly to Dr. Trueta, who has so clamorously and emphatically propounded these methods of early wound excision, drainage, and plaster fixation which are now becoming so widely known and practised so effectively, and with such good results, that the amount of suffering and the mortality from complications of wounds inflicted in this war have already been considerably less than they were in those of the last and so-called Great War of 1914-18. In the Spanish War he taught us that first aid for wounds should be avoided wherever possible, that the first intervention should be the main intervention, and wounds should be dressed as little as possible. He here describes what he calls his "five-point programme," consisting of (1) prompt surgical treatment; (2) cleansing of the wound; (3) excision of the wound; (4) provision of drainage; and (5) immobilization in a plaster-of-Paris cast. The methods of putting into operation the steps of this programme are illustrated by photographs of patients undergoing treatment. This five-point programme, with the details of how it can be carried out, constitutes the second and perhaps chief part of the present monograph: the former part is concerned with the pathology of wounds and the treatment of the wounded patient; and here we find very valuable discussions of such questions as infection, gas gangrene, tetanus, and shock.

The book is admirably printed in clear type, with excellent illustrations, and contains a comprehensive bibliography, and if its price appears high its quality is surprising for wartime and would appear to merit it. We venture to prophesy that it will become a classic of which most surgeons will want to possess a first edition. It is, perhaps, the most important monograph the war has so far produced. Embodying those correct biological principles which, as its author tells us, have been upheld by those men "who, believing in the benevolence of a Divine purpose, regarded themselves as its humble instruments," it marks another important transition period in surgical practice.

PAEDIATRIC GYNAECOLOGY

Pediatric Gynecology. By Goodrich C. Schauffler, M.D. (Pp. 384. $5.00 or 27s. 6d.) Chicago: The Year Book Publishers, Inc.; London: H. K. Lewis and Co. 1942.

This is a most interesting book, but it is more: it is a most useful one which should have a wide appeal. The everyday problems of the child with vaginal discharge, enuresis, pubertal bleeding, and pyelitis are but a few which the harassed physician is apt to treat indifferently and ineffectively for want of adequate direction and encouragement. Eighteen years ago Schauffler was faced with his first case of gonococcal vaginitis in a child of 3. After searching the textbooks and the literature for help he realized that this was not easy to find. Through the years that followed he made a careful and detached study of the female in infancy, childhood, and adolescence. Sixteen years of wide experience provided an excellent background and ample material from which to write a book devoted entirely to paediatric gynaecology.

The book is a comprehensive one. It opens with a concise review of the psychological factors so important to the successful handling of these cases. The technique of examination is then discussed in some detail, with due emphasis on points of practical importance, and a careful and well-illustrated account is given of the anatomy of the external genitalia, the vagina, and the cervix. The subjects of masturbation, vaginitis, and foreign bodies in the vagina are well handled in these same chapters. A comprehensive study follows of the menarche and those disorders of adolescence such as menorrhagia, metrorrhagia, and dysmenorrhoea. Pelvic viscera and pelvic peritonitis are the subjects of a separate chapter. A few pages are devoted to the consideration of pre-operative preparation, general principles of operative technique, and post-operative care, and these are followed by two excellent chapters dealing with lesions of the urinary tract and the lower bowel. The book concludes with a helpful discussion of social service and medico-legal problems.

The author is to be congratulated on his pioneer work and on the book he has written. It will be an excellent guide to all who are interested in this most important aspect of medical practice.

BOOKLETS ON FIRST AID

Air Raid First Aid. By W. A. Ashford, with foreword by W. A. Muir, M.D., D.P.H. (Pp. 46. 1s. 6d.) London: Williams and Norgate. 1942.

Emergency Street First Aid for Air-Raid Casualties. By Rufus Harris, M.R.C.S., L.R.C.P., First Aid Commandant, Exeter City Casualties Service. (Pp. 51.) Exeter: A. Wheaton and Co.

Of the making of "first-aid" books and booklets there appears to be no end. Each one has its merits, but each has its demerits. Notices of two which appeared in the first half of 1942 are given here.

Air Raid First Aid, by W. A. Ashford, is convenient for the pocket, written by a non-medical man, and commended by a medical officer of health. Its object is to present details of "reduced" treatment to be carried out at an incident. Taken as a whole it is clear, concise, dogmatic, and full of excellent suggestions and practical points. The question of "priority" in the treatment of casualties at a bombed site is answered well. It is perhaps a pity that "Bleeding, external," is separated from "Bleeding, internal," by a full chapter on wounds. By a few quotations it is not intended to disparage the contents but help towards improvement. Asphyxia in itself is not "want of fresh air"; it is the result of such a deprivation. Apropos of this a remarkable statement appears on page 45, amid some interesting "Odds and Ends." "Asphyxia. If you can't get a patient into the fresh air, take fresh air to the patient. A garden hose will do"! Fractures should be styled "closed" and "open," not "simple" and "compound." One thumb correctly applied in cases of arterial bleeding is sufficient; thumbs, or fingers, in the duplicate are not needed. The statement "Remember, a tourniquet is only required when a main artery is known to be severed," is not true; an artery may bleed furiously when only partially cut across. It is asserted on page 24 that the sympathetic nerves control the diaphragm and respiratory muscles, but neither anatomy nor physiology bears this out. A perusal of the booklet will repay the cost.

Emergency Street First Aid for Air-Raid Casualties, by Dr. Rufus Harris, has 51 pages and many diagrams. Not much perhaps new in this booklet, but the old clearly put. Some interesting details are given as to the correct position for a casualty on a stretcher. Attention is drawn to the fact that continued oozing of blood may lead to serious consequences if not discovered and dealt with. Good general rules for the first-aid treatment of fractures are given, but again the words "simple" and "compound" are wrongly used. In capitals on page 8 occur the words "GIVE NO STIMULANT" followed by no idea as to whether this means "Give no alcohol" or "No stimulants are ever suitable to be given." Alcohol is not a "stimulant," but "hot tea" is. No remark is made as to the value of morphine in the relief of pain in burns and scalds. Taken with the extant textbooks this work forms a useful adjunct.

Notes on Books

The series "Britain in Pictures," in which *British Rebels and Reformers* appears, has won for itself a special position which this volume well maintains by its 8 beautiful colour plates and other drawings (William Collins; 4s. 6d.). As might be expected, the versatile Dr. HARRY ROBERTS is quite at home with his subject. He evidently believes with Jefferson that "a little rebellion now and then is a good thing." His good but necessarily rapid survey of the conditions which produced some of our national political and social rebels and reformers supports his statement that our history shows that it is love of justice rather than of riches, rather even than of liberty, that stirs the average Englishman to action. Dr. Roberts distinguishes between the rebel whose only weapon was revolt and the reformer who was able to use constitutional means of redress. Sympathetic as he is by temperament to the rebel, he does not fail to point out that responsibilities follow as a necessary consequence of power—a point that many of the rebels overlooked. He also shows that most of the rebellions and nearly all the reforms in this country have been backed by individuals who were not personally affected by the grievances they sought to remedy—Florence Nightingale and Lord Shaftesbury are good examples. There is nothing specifically medical in this book, but, as the author says, every Englishman should be interested in the things it deals with, for "politics, ultimately, is concerned, not with States and abstract policy, but with men and women who are born, see visions, fall in love and die"—a doctrine which is not without its implications in these days when "planning" is the fashionable cure-all and the individual runs a risk of being overlooked.

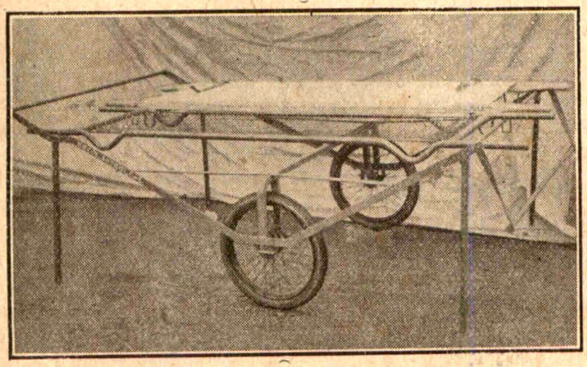
Preparations and Appliances

A WHEELED STRETCHER OR EQUIPMENT CARRIER

Dr. K. VERNON BAILEY, M.R.C.P., writes:

The stretcher carrier described below was primarily evolved to deal with Home Guard casualties and is based largely upon Home Guard needs, but it obviously would be of great value also for service with the Regular infantry and R.A.M.C. forces.

The main disadvantages of the hand-carried stretcher are: (1) its limitations over a long distance; frequent rests for the bearers become necessary and the slow and uneven progress detracts from the patient's prospects; (2) its extravagant demand on personnel; a heavy casualty may require four men to transport the loaded stretcher a matter of 300 yards, at the end of which time the bearers are temporarily exhausted. Moreover, in open contact with the enemy it is not always to be expected that casualty collecting points will be within convenient hand-carrying distance from forward positions; those that are may, during an engagement, either become further removed by the advance of these positions or be put out of action altogether. Further, motorized ambulance transports may not be able always to approach directly to the position of forward collecting points to complete the evacuation. Too great a reliability is placed on their being able to do this in the organization of Home Guard defence and too little consideration given to the following facts: (1) the number of casualty collecting points is large (on a platoon basis); (2) their exact positions may be difficult to find; (3) the number of motor ambulances is limited; (4) motor ambulances themselves require either roads or a relatively smooth surface over which to travel; and (5) the forward area to a depth of a mile or more is under fire.



An area some one to three miles in depth behind the line of contact with the enemy is likely to be embarrassed in the matter of communication, congested so far as road traffic is concerned, and continually subjected to the effects of the action in progress. Under these conditions it is essential that casualties of the first priority should be evacuated immediately to a position of relative safety, where they can receive adequate temporary treatment, or from which they can be transported to a hospital or clearing station. The best method of doing this is to use a special hand-propelled wheeled stretcher carrier. The most efficient and economical type of such carrier is one which is light to handle, easy to transport when unloaded, strong enough to take the weight of two loaded stretchers, and can be loaded and propelled by two bearers.

Suggested Design for Metal Carrier

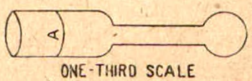
A light carrier has been made to this design by Lieut.-Col. Crooke, commanding 49 Lancs H.G. The technical description is as follows. The framework is so constructed of metal sections that it is flexible in itself; it is mounted on 8 coil springs, each supporting a load of 50 lb., transferring the load to the road wheels fitted with 20 in. by 2 in. by 1¾ in. pneumatic tyres which can be inflated by a cycle pump. There is a fixed handle-bar at one end for control, and a folding handle-bar at the other end for traction. Four supports are provided, one at each corner held in a folded position with a link and readily manipulated. The axle is arranged to give the maximum ground clearance. The wheels can be removed in the same manner as a cycle wheel. The general service and civil defence stretchers can be used. The carrier is painted with anti-gas paint and weighs 100 lb.

The springing minimizes all jolts or jarring during transport, and the carrier can be dismantled for transportation by simply dropping it out of the wheels, which are packed separately. It is quickly and simply loaded by placing the stretcher on the two transverse cross-bars, which fit accurately against their runners, and it is easily controlled by two men. The corner stands are quickly released to steady the carrier for loading or in an emergency, and are rapidly secured again in place. It is important to place the stretchers with the heads of the patients at the pulling-end of the carrier; this has the effect of weighing down the pulling-end and thus enabling the bearer at the pushing-end to lean on the bar and so exert easy pressure. The carrier loaded with two stretchers, each bearing a patient weighing approximately 11½ st., plus their full equipment, including great-coats, blankets, etc., was transported over a distance of two miles (mostly uphill and including a 200-yard hill of 1 in 6 gradient) in under 30 minutes without undue hurry, exertion, or fatigue. Barriers which could not be surmounted by a motor ambulance were negotiated by unloading the carrier, transporting the loaded stretchers and carrier separately by hand, and reloading on the other side.

CENTRIFUGE TUBE FOR COLLECTION OF LEUCOCYTES

Dr. M. A. GOHAR, Ph.D., M.R.C.P., writes from the Faculty of Medicine, Cairo:

For the preparation of a leucocyte suspension, one of the usual procedures is to centrifuge citrated blood in an ordinary centrifuge tube and to collect the greyish layer that floats on the surface of the red blood corpuscles. This, however, is not always easy since the film is so thin that, when taken, one usually finds that the great majority of the cells are red blood corpuscles and that the leucocytes are rather scanty. The cause of this difficulty is that the film collects on a big surface. If this area could be made smaller, the thickness of the film would obviously be increased and the leucocytes would therefore be much easier to collect. This led me to suggest the use of a centrifuge tube having the shape illustrated in the figure. It is needless to say that it should be made from the strong glass from which centrifuge tubes are usually made. It has actually been made locally to my satisfaction in the glass factory of Messrs. Sayed Yasin and Co., Cairo.



ONE-THIRD SCALE

The tube is filled with citrated blood up to the mark A and centrifuged. The upper level of the corpuscles falls in the narrower part of the tube. Since the surface area here is small the film of leucocytes on the top of the red blood corpuscles is relatively thick and is easier to collect than a film in a wide ordinary centrifuge tube with a wide surface area.

MEDICAL APPLICATIONS OF THE CYCLOTRON

Popular interest in the cyclotron has been stimulated by its description as an "atom-smasher," but a more accurate name for its effects would be "nuclear transformation."[1] With the discovery of radio-activity the existence of natural transmutation of atoms was demonstrated, and the first artificial transmutation (of nitrogen into oxygen) performed by Rutherford in 1919 directed attention to the means of energizing particles to such a degree as would enable them to penetrate the nuclear barrier. While the methods of attaining very high voltages in order to give a particle high energy by a single big push made steady progress, J. H. Lawrence experimented with the idea of using much lower voltages tuned to give the particle a series of pushes. Thus the cyclotron emerged—an apparatus in which the particle is kept moving in a circular path by a magnetic field and intermittently accelerated by an electrical field. The particles move inside two hollow semicircular electrodes placed between the poles of an electromagnet, and are accelerated by an oscillating potential applied to the electrodes every time they cross the central gap between them. The angular velocity of the particle produced by the magnetic field is constant, but the successive accelerations of its linear velocity produced by the electrical field cause it to move in an ever-widening flat spiral. Its ultimate energy is thus limited only by the diameter of the hollow electrodes. Lawrence's early model was 11 in. in diameter, and produced protons with an energy of 1.25 million electron-volts (mev.). Then came a 27-in. cyclotron with an 80-ton magnet, subsequently increased to 37 in., and giving particles with 8 mev. energy. The discovery of the neutron by Chadwick in 1932 and the isolation of heavy hydrogen by Urey in the same year greatly facilitated atomic transformations, for, whereas the proton ${}_1H^1$ has to overcome the repulsion exerted by the positively charged nucleus of the atom, the neutron of the deuteron particle ${}_1H^2$ meets with no such opposition. (The superscription refers to the mass of the atom and the subscription to its charge: thus the deuteron ${}_1H^2$ has a mass of 2 and a single positive charge.)

Atomic transformations result in excited atoms which emit energy in various forms—that is, artificial radioactivity is produced. For example, a proton captured by a lithium nucleus results in an unstable beryllium nucleus, which splits into two α-particles (or helium nuclei) with an energy of 8.5 mev.: ${}_1H^1+{}_3Li^7\rightarrow{}_4Be^8\rightarrow 2\,{}_2He^4$. The neutron of a high-speed deuteron may be captured by a phosphorus nucleus, and the radio-active phosphorus then emits a β-particle (or electron) with 1.7 mev. energy and becomes sulphur: ${}_1H^2+{}_{15}P^{31}\rightarrow{}_1H^1+{}_{15}P^{32}\rightarrow{}_{16}S^{32}+{}_{-1}e^0$. Or the whole deuteron may enter a beryllium nucleus, yielding a very unstable boron nucleus, which at once emits a neutron of very high energy, 21 mev.: ${}_1H^2+{}_4Be^9\rightarrow{}_5B^{11}\rightarrow{}_5B^{10}+{}_0n^1$. Thirteen types of nuclear reaction have been observed, and radio-active isotopes of every known element have been produced. With the 37-in. cyclotron, however, the yields of artificially radioactive elements were small, and in 1939 a 60-in. cyclotron with a 200-ton magnet was completed specifically for medical application. Producing particles with 16 mev. energy, its yield of radio-active elements is some five times that of the 37-in. cyclotron. A giant 184-in. is now nearing completion, with a magnet weighing 4,000 tons; it will produce deuterons with an energy of 100 mev., giving thirty-five times the yield of radio-active substances from the 60-in. "medical" cyclotron. But more than a greatly increased yield is expected from this giant cyclotron: the energy of its particles will approximate to that observed in cosmic ray phenomena, so that new atomic processes are likely to happen. When mass disappears, energy appears in its place: according to Einstein's theory, the energy released is equal to the mass multiplied by the square of the velocity of light—i.e., 9×10^{20}—and this relationship has been verified for the proton–lithium reaction producing two high-speed α-particles. The hundred-million-volt cyclotron will certainly be used for investigating the possibilities of atomic power.

The three major fields of biological study developed about the cyclotron have been surveyed by Hodges,[2] and formed the subject of a symposium at a meeting of the Radiological Society of North America.[3] First, there is the use of a radio-active element to trace the absorption, utilization, and excretion of its stable isotope by the body in both health and disease.[4] Secondly, there is the therapeutic effect of the radiations emitted by radio-active substances internally administered. Thirdly, beams of both fast and slow neutrons are being used in the treatment of cancer in a manner similar to *x* rays and γ rays in external radiation therapy.[5] Metabolic studies by the classical methods of chemistry and physics need relatively large quantities of the elements to be investigated; these disturb the normal balance of such elements in the body, and the methods employed cannot differentiate between what has been administered and what was already in the body. The radio-active tracer substance reveals the metabolism of an element with a sensitivity several million times greater than that shown by chemical methods, by the measurement of the radio-activity of organs and tissues either *in situ* or in samples of tissues after removal from the body. In the latter case, also, an autoradiograph of a thin slice of tissue can be directly compared with the stained histological preparation. For example,[6] this method has shown that iodine is taken up in larger amounts by hyperplastic thyroid cells than by the normal cells, but that it is not taken up at all by cancerous thyroid cells. Thus, while radio-active iodine may be of value in the treatment of thyrotoxicosis, it is unlikely to help in the destruction of malignant disease of the thyroid. The rapidity of the metabolic processes of the body is well illustrated by the fact that within four hours of administration over nine-tenths of the radio-active iodine has been combined into the organic compounds thyroxine and di-iodotyrosine. Incidental to the researches on iodine metabolism, the missing element 85, belonging to the halogen series and not yet found in Nature, has been artificially produced and found to be radio-active. Its halogen nature was confirmed by its selective absorption by the thyroid gland, though to an extent only about one-third of that of iodine.

Only weak activities of radio-active calcium have been available, but radio-active strontium can be readily prepared in large amounts and emits energetic β rays, and has the useful half-life period of 55 days. It is selectively deposited in actively growing bone, including bone tumours, so that it is likely to have therapeutic applications in adults suffering from osteogenic sarcoma; the possibility of destroying early pulmonary metastases at once presents itself. The use of radio-active carbon has upset two accepted theories—of the photosynthesis of carbohydrates by green plants and of the manufacture of glycogen in the liver from lactic acid. Ruben and Kamen[7] have shown that the initial reaction involving each assimilated carbon dioxide molecule is its reduction to a carboxylic acid group, and that this is a non-photochemical reaction. Hastings administered lactic acid containing radio-active carbon atoms, but none of these labelled carbon atoms could be detected in the liver glycogen; when sodium carbonate was used as the vehicle for the radio-active carbon, all the labelled carbon was recovered from subsequently elaborated glycogen. These examples are sufficient to illustrate Hamilton's conclusion that, while the classical procedures of chemistry and physics yield a static picture of biochemical processes, the radio-active tracers reveal the dynamic pattern of the chemical integrations taking place in the living cell.

[6] Hamilton, J. G., *Radiology*, 1942, **39**, 541.

Some instances of the practical application of this new physical knowledge have already been given. Naturally the possibility of applying radiation selectively to malignant cells is one that has aroused the most intense interest. Radio-active phosphorus is selectively accumulated in the nuclei of rapidly multiplying cells, and the results of its therapeutic use in 222 patients with leukaemia and allied diseases are reported by Low-Beer, Lawrence, and Stone.[8] Trials of different methods of dosage suggest that the best results follow intravenous injection of small weekly doses sufficient to maintain a radio-active level of from 3 to 8 millicuries. The clinical results in polycythaemia vera and multiple myeloma are much better than from any other known treatment; in leukaemia they are at least as good as from *x*-ray therapy; but in Hodgkin's disease they are disappointing—a combination of deep *x*-ray therapy and radio-active phosphorus is now being tried. The results in 22 cases of lymphosarcoma reported by Kenney and Craver are also rather disappointing, in that the response of the disease to radio-active phosphorus ran parallel to that to *x*-ray therapy, so that where *x* rays had failed to control the disease P^{32} also failed. A valuable report by Stone and Larkin[9] on radiotherapy by fast neutrons establishes the degree of dermal, mucosal, and general reactions to be expected from given doses. Curative results were not anticipated, as the 120 patients so far treated were chosen because of their unsuitability for treatment by surgery, radium, or *x* rays. The neutron beam was produced in the 60-in. cyclotron by the bombardment of a beryllium target with 16 mev. deuterons, giving neutrons with energies up to 21 mev. and γ rays; after passage through 3 cm. Pb the beam comprises 95% neutrons and 5% γ rays. There is no significant scatter, so that the "air-dose" and the "skin-dose" are the same; the depth dose at 10 cm. for a 10×10 cm. field is 40% of the surface dose. At the end of treatment about 17% of the patients showed complete regression and 48% partial regression of the tumour; perhaps the most encouraging observation was that epitheliomatous metastases in the lymph glands of the neck responded better than the primary tumour; while on the debit side was the persistence of ulceration at the site of the primary tumour, even though biopsy from the margin of the ulcer showed no evidence of cancer. It looks as if the intensity of ionization in the tissues is such as to destroy impartially both the cancer cells and the stroma, but different combinations of the dose, time, and intensity factors will require trial before the place of fast neutrons in the radiotherapy of cancer can be assessed.

THE CAUSE OF MYASTHENIA GRAVIS

Recent advances in physiological knowledge have seldom been applied to the study of disease so readily as in the case of the chemical factors subserving transmission of nervous impulse at the myoneural junction. As each step in knowledge in this field has been made it has been applied to diseases thought to be caused by disorders at the myoneural junction, of which myasthenia gravis is the outstanding example. In an orderly series of papers from the Johns Hopkins Hospital[1 2 3 4] Harvey and his colleagues have continued to study the mechanism of the transmission of impulse from nerve to muscle in man by the investigation of normal and abnormal subjects. They point out that the evidence that the disorder in myasthenia gravis is at the myoneural junction is overwhelming, and postulate three possible forms which this abnormality may assume. First, there may be an excessive concentration of cholinesterase, which by hydrolysing the released acetylcholine prevents the sustained transmission of nervous impulse and consequently muscular contraction. Secondly, the excitatory threshold of the muscle end-plate to the normal quantity of acetylcholine released by each nerve impulse reaching the neuromuscular junction might be raised. Thirdly, each impulse reaching the neuromuscular junction might fail to release a normal amount of the transmitting agent, causing in effect a physiological denervation. Harvey and his co-workers show that, whereas in normals intra-arterial injection of prostigmine caused a diminution of the contraction of striped muscle, it causes an increase in myasthenic subjects. When a retaining cuff is released the effect spreads from the muscles nourished by the artery to muscles elsewhere in the body. When acetylcholine is injected into an artery of a normal subject who has received prostigmine previously, there are flushing and sweating of the distal extremity, with immediate deep pain and weakness of muscles, followed by fibrillation. This, as they explain earlier, is due to the paralysing effect of too great a concentration of acetylcholine at the junction, made possible in normal people by the presence of prostigmine, which inhibits the destruction of the acetylcholine by the cholinesterase normally in the blood stream. In myasthenics, on the other hand, although flushing, sweating, and pain are present as in normal persons, violent muscular contractions, going on to spasm similar to the carpopedal spasm of tetany, occur in place of the muscular weakness seen in normal subjects. These contractions are much more powerful than would be possible with purely voluntary contraction of the muscles. In the myasthenic, also, the rapid, flickering asynchronous fasciculations which they observed in the normal subjects were not encountered.

The authors proceed to list the many points of resemblance between myasthenia gravis and partial curarization, but they go on to show that, whereas the myasthenic muscle is exquisitely sensitive to acetylcholine, the partly curarized muscle is much less sensitive to it than is normal muscle. The great sensitivity of completely denervated muscle to injected acetylcholine is well known,[5] and the similarity between the physiological behaviour of denervated and of myasthenic muscle when exposed to the substances modifying transmission at the myoneural junction is close. Harvey and his colleagues conclude that the evidence they present supports the view that in myasthenia gravis there is a reduction in the amount of acetylcholine released at the junction. This may be due to one of three things: first, a reduction in the store of the transmitter or its precursor; secondly, unusual susceptibility to abnormally

rapid destruction; and, thirdly, a normal store of transmitting substance which, although available, might be blocked in its action by another substance. They present evidence in support of the third possibility.

As myasthenia gravis is characterized by the occurrence of spontaneous remissions and the defect in transmission is temporarily repaired by other substances, the reversible character of the disorder is emphasized. From the mass of evidence they produce it seems reasonable to assume on physiological grounds that some independent inhibitor substance released into the circulation in varying amounts might be responsible for the functional defect which is found. Gammon, Harvey, and Masland[6] have shown that this hypothetical substance might well be derived from the thymus gland. Abnormality of the thymus is found at necropsy in a very large proportion of myasthenics, and the results of surgical thymectomy in severe myasthenics, carried out in this country by Keynes,[7] have in some cases been brilliant. The whole story is not yet known, and the more acute and severe myasthenics, with generalized weakness, seem to benefit most by operative removal of the thymus. Those with weakness confined to muscles having a bulbar innervation do not respond so well as those with weakness of spinal muscles. Nevertheless it is encouraging to find the results of physiological research being translated into therapeutic achievement even if the full effects of surgical intervention are not yet understood.

POLIOMYELITIS VIRUS IN WATER

Poliomyelitis virus has been demonstrated in the faeces of persons suffering from the disease and has been shown to persist for a long time in sewage. The gastro-intestinal tract is now recognized as a portal of entry for the virus, so that drinking-water contaminated secondarily from sewage must be looked upon as a potential source of infection, though no case has, as yet, been traced directly to such water. Poliomyelitis virus is known to persist for 100 days and more in sterile water stored in the dark, and modern methods of chlorination leave it unaffected. Carlson, Ridenour, and McKhann[8] have lately investigated whether the water-purification methods in common use will remove the virus from artificially infected water. They used a neurotropic virus pathogenic to mice—apparently an adapted poliomyelitis strain. Coagulation and sedimentation procedures with lime and alum caused but a slight reduction of the amount of virus in suspension, and this reduction was roughly proportional to the amount of virus present. During these experiments it was noted that this neurotropic virus withstood a pH range of 3.5 to 8.0. Sand filtration was carried out in the laboratory in a model filter with constant head of water. The virus was not held back by sand filtration alone, but when large quantities of alum floc were allowed to impregnate the surface layers of the sand filter, with consequent diminution of filter flow, only one mouse of 54 inoculated with the filtered water developed paralysis, while control groups of mice were paralysed, showing the virus to be present and active in the supernatant water. It was found that a large accumulation of floc was required to hold back the virus, because, in a later experiment, a measured layer of floc of 1/8 in. thickness did not restrain it. Partial adsorption of the virus on activated charcoal was demonstrated in concentrations of 10, 25, and 50 parts per million in water. Injection of the charcoal into mice showed the virus to be concentrated on the particles. Suspensions stored in tap water in the refrigerator remained viable for more than a hundred days, and aeration had little apparent effect on the virus. Irradiation with ultra-violet light effected a big reduction of virus suspension in water. Of the 36 mice used in the irradiation experiments only 3 became paralysed and died, while all but 1 of the control group of 18 animals which received a 1 in 300 dilution of untreated virus became paralysed. Direct sunlight did not destroy the virus as effectively as did ultra-violet light, which was, in fact, the most effective of all the water-purification methods investigated.

CASTRATION FOR PROSTATIC CARCINOMA

In the spring of 1941 Huggins and his co-workers reported a series of cases of carcinoma of the prostate which had been treated either by castration or by the administration of oestrogen, or by both methods combined. The results were unexpectedly favourable, even when extensive bony metastases existed. Huggins assessed his results chiefly by clinical data but also by the fall of acid phosphatase, which is usually much increased in cases of prostatic carcinoma. Since the publication of his paper this form of treatment has been adopted by many other surgeons. R. Chute and A. T. Willetts have recently reported[1] on thirty-seven cases treated by these means. Only one patient would appear to have received no benefit. Beneficial results included rapid, effective, and lasting relief from the pain of metastases, increase in weight, and improvement in appetite, strength, and general well-being. Nine out of 13 cases with retention were able to pass urine after treatment by orchidectomy and stilboestrol. Determination of the acid phosphatase showed that when its level was above normal it fell rapidly after castration, and still further with the giving of stilboestrol. No dangerous or harmful effects were noted, though, as was to be expected, libido and power of erection disappeared in most cases. The results of stilboestrol therapy were in every way as good as those obtained by castration, but since the effect of stilboestrol lasted only while it was being given, the favourable action obtained from castration was more permanent. For this reason alone it has a considerable advantage. Quite naturally some patients dislike the idea of such an operation, and the technique suggested by L. W. Riba[2] avoids some of the psychological disadvantages inherent in castration. The operation is performed as follows: The anterior scrotal wall is infiltrated with 1% novocain and 10 c.cm. of the anaesthetic injected directly into each spermatic cord. The testicle is then delivered through a 4 or 5 cm. incision and the anterior surface of the tunica vaginalis and albuginea incised. The exposed parenchyma can easily be removed through this incision by blunt dissection. Bleeding is easily controlled by ligature, and when haemostasis has been secured the incised capsule of the testicle is sutured. Both testicles can be treated through the same median scrotal incision. As a rule the patient is unaware of their absence.

RIBOFLAVIN AND CORNEAL VASCULARIZATION

The syndrome of ariboflavinosis, or riboflavin deficiency, was first described in 1938 by Sebrell and Butler,[3] who recorded the angular stomatitis, reddening, fissuring, and desquamation of the lips, and the seborrhoeic lesions of the nose, eyelids, and ears that occur in this syndrome. In 1940 Kruse and his colleagues[4] [5] added to these appearances a frequently fissured magenta-coloured tongue with flattened papillae, and for the first time also described certain ocular lesions characteristic of ariboflavinosis—roughness of the eyelids, photophobia, inability to see in a dim light, lacrimation, impairment of visual acuity, keratitis, and corneal vascularization. They stated that the earliest and most common sign of ariboflavinosis is circumcorneal injection, which if not grossly visible is seen on slit-lamp examination. Since 1940 corneal vascularization has come to be regarded as a certain diagnostic sign of ariboflavinosis, and American nutrition surveys[6] have used it as an index of riboflavin nutrition. Recently, however, the value of this sign has been questioned in both this country and America. In an article in this *Journal* Scarborough[7] recorded an incidence of circumcorneal injection of 34% in a series of 204 unselected out-patients in Edinburgh (68% in patients over 50), and Sandstead[8] has found the condition extremely common in school children and young adults in America, the incidence ranging from 80 to 93% in the various groups studied. In Sandstead's cases riboflavin in doses of 5 mg. daily caused no significant change in the degree of corneal vascularization. Scarborough made a similar observation. At present, therefore, corneal vascularization is a doubtful diagnostic sign of riboflavin deficiency unless supported by other clinical findings such as angular stomatitis, reddening and desquamation of the lips, ocular symptoms, and the seborrhoeic dermatosis of the face.

The supposed association between rosacea keratitis and ariboflavinosis has also been challenged. In 1940 Eckhardt and Johnson[9] suggested that rosacea keratitis resulted from riboflavin deficiency because of the improvement after administration of riboflavin and because of the possibility that the telangiectasia and corneal vascularization of rosacea keratitis might be physiological responses of the blood vessels to deficient oxidation resulting from the failure of the flavo-protein enzyme system, of which riboflavin is a component. These authors claimed to have cured cases of rosacea keratitis with injections of 1 to 2 mg. of riboflavin. Recently Fish[10] has been unable to verify this claim. In 40 out of 45 cases of rosacea keratitis she was unable to find the type of vascularization described by the American authors as characteristic of ariboflavinosis. Treatment with riboflavin alone was unsuccessful; many of the patients actually became worse owing to the withdrawal of atropine. The lesions of controls healed under routine treatment. It has now been established that the concentration of riboflavin in the corneal epithelium of the ox is very high, and it may be that in patients already suffering from ariboflavinosis and with corneal lesions the administration of the vitamin may promote healing; this might explain its beneficial action in the cases described by Eckhardt and Johnson.

RETINAL VENOUS CHANGES IN DIABETES

Ophthalmoscopic findings in cardiovascular lesions have the great drawback that they are but poorly elucidated by histological studies, for these are exceptional. It is one of the merits of the Mackenzie Memorial Lecture by Prof. A. J. Ballantyne[11] that the wealth of clinical detail he reports is substantiated by pathological studies. Of necessity there is much that is conjectural in his discussion of changes in the lumen of vessels, comprising, among others, such an entity as transitory spastic contraction. His insistence on checking appearances by established pathological data does, however, give validity to his discussion where no such evidence is available. Thus he is able to remind us that a retinal artery which looks white to the ophthalmoscope is not necessarily an obliterated artery, for qualitative changes in the vessel wall as well as obliteration of the lumen can give this effect. His critical survey of our knowledge of these and allied appearances, such as those seen at the arteriovenous crossings, lends point to his personal observations. He rightly states that, while much attention has been given to changes in the arteries, relatively little has been allowed to changes in the veins; yet, as he shows, the veins, too, can undergo spasm. But what is particularly significant is the series of changes in retinal veins that he ascribes with a high degree of probability as pathognomonic of diabetes. The picture, as he presents it, is characteristic enough. There is irregular beading of a gross type in the larger veins, tending to produce loops which, histologically, he has found to be pre-retinal as well as retinal. The obvious interference in venous flow shows itself in secondary retinal changes. Gross venous obstruction, such as is seen in thrombosis of the central vein, is not a feature. The attention he focuses on the veins in diabetes may help to explain some of the characteristic vascular lesions the clinician recognizes as diabetic without being able to distinguish them clearly from somewhat similar changes in simple retinal arteriosclerosis.

HIPPURIC ACID SYNTHESIS AND LIVER FUNCTION

The hippuric acid test of liver function—based upon the excretion of hippuric acid in the urine after ingestion of sodium benzoate—is noticeably less popular here than in the United States, where it was introduced by Quick.[1] This may be due to its theoretical disadvantages, such as the uncertain influence on the result of rates of absorption and excretion. The former may be obviated by giving the sodium benzoate intravenously,[2] but renal damage must always be considered and may partly account for the impaired excretion found in obstructive jaundice and after surgical operations.[3] Nevertheless there are many cases in which the kidneys can be trusted to play their part satisfactorily, and the relative convenience of the test is a strong point in its favour. A recent report by Rennie[4] from Glasgow is therefore of special interest. Using the oral technique, he found low excretion in 13 out of 17 cases of infective hepatitis, in 5 out of 5 cases of acute toxic hepatitis, in 12 out of 14 cases of hepatic carcinomatosis, in 13 out of 14 cases of cirrhosis, in 8 out of 10 cases of obstructive jaundice, and in 4 out of 24 cases of cholecystitis. This leaves little doubt that the test is a sensitive indicator of hepatic damage, but raises the question of the way in which it is likely to be clinically useful. It is evident that the diagnostic possibilities are limited, similar results being obtained in all types of liver disease, including obstructive jaundice. It may evidently be useful in revealing latent liver damage—e.g., in hyperthyroidism[5]—in studying the impaired function in known hepatic diseases, and in assessing recovery from toxic and infective hepatitis.[4] The test has been used prognostically by Boyce[3] in obstructive jaundice and in various surgical conditions, and the statement has been made by Delor and Reinhart[6] that patients excreting less than 2 grammes are usually a poor operative risk. This important claim merits further investigation in view of the possibility of improving liver function in these cases by suitable pre-operative therapy.

SOME OBSERVATIONS RELATING TO THE PLANNING OF MEDICAL EDUCATION

BY

FRANCIS DAVIES, M.D., D.Sc.

Department of Anatomy, University of Sheffield

In recent years much has been written, and a great deal of disquiet expressed, concerning the present status and the future planning of medical education. Various committees are to-day considering the general changes in medical education which appear to them to be necessary, and universities and medical schools throughout the country have been invited to report their views on these problems to the Interdepartmental Committee on Medical Schools of the Ministry of Health. It may be observed that one body which is taking upon itself the onus of investigating these matters plays no part at all in the actual teaching of the medical student. The time seems ripe for a frank statement on considerations which do not appear in the foreground of previous writings on these problems, but which should receive careful attention in the present deliberations. They comprise, first, the quality of the prospective entrant to the medical profession, and, secondly, the adverse influence which the existing examination system (at least in some subjects) has upon the "education" of the medical student.

The Curriculum

Some rigidly separate medical education into two sections—namely, scientific education and vocational instruction—and lay emphasis on the necessity for paying particular attention to the latter at the expense of almost complete elimination of the former, on the ground that we are instructing students the great majority of whom are destined to become general medical practitioners. The implication may be drawn that the curriculum should be so fashioned that the bare minimum must be taught in order that the type of student with whom we have to deal can safely and relatively easily cope with it. Now, it must be the opinion of every teacher of some years' experience that the better students take the present curriculum in their stride; they are even avid for more information, over and above that given to their contemporary classmates in the formal lectures and practical classes, and, by a stimulating and progressive teacher, they are readily encouraged to read widely around the narrow confines of the formal classes they attend. On the other hand, it is sadly true that too high a proportion of our medical students are not up to the standard which should be required of a person who is to be entrusted with matters relating to the health of the community. These students just manage to crawl along the curriculum, failing the examinations sprinkled through the course time after time, till eventually, after descent in many cases from degree to diploma courses, they scrape through a final qualifying examination. A relatively long tail of such students is found, particularly in schools catering for large numbers, where nothing approaching individual attention is attained. Most of these students succeed in passing the several examinations after two or more attempts at each, and, even when they eventually pass, they just manage to obtain one or two marks over the minimum pass-mark.

This state of affairs must certainly be considered unsatisfactory. It is surely not the desire of those responsible for remodelling the curriculum to bring down the standard or scope of the various subjects to the level of such students. We must face the fact, known to university teachers in the pre-clinical years, that their colleagues in the other faculties of the university are of the opinion that many students in the Faculty of Medicine are not of the best quality, and, indeed, some of these teachers who deal with medical students in the first year of their course are not unwilling to state that many medical students are not of the standard of the majority of those taking university courses in other faculties. Furthermore, relevant to the present discussion, it must be a common experience for teachers in the Medical Faculty to learn from some of their colleagues in other faculties (many of whom have attained eminence in their particular subject) that they themselves would have liked to enter the medical profession in their earlier years, but were precluded from doing so by financial considerations.

The Prospective Medical Student

It appears to me that a radical alteration which is urgently needed is to eliminate financial obstacles and thereby place ourselves in the position of being able to choose the best talents among prospective students from all walks of life. As a corollary to this, the weakling should be ruthlessly eliminated *in the early years of the course.* By such means the quality of the "raw material" could be considerably improved and a high-standard curriculum evolved, the student being educated to this standard and not the standard degraded to the level of a second-rate student. The manner in which the financial obstacles may be overcome needs consideration; and, while undertaking this, it must be borne in mind that the present trend of economic developments (e.g., as outlined in the Beveridge report) will probably lead to the demand for a considerable increase in the number of doctors to qualify each year, entailing the calling for supplies of suitable students from a wider section of the population. The following suggestion is made with the appreciation that others may be formulated as more economically sound, although, so far as I can see, the general principle should be readily acceptable.

In the discussion by the General Medical Council (Winter Session, 1942) of the draft memorandum from the subcommittee appointed to prepare evidence for the departmental committee of the Board of Education, Sir Farquhar Buzzard expressed his opinion that one of the chief causes of early specialization (i.e., in the schools) was the scholarship and the competition between schools for this purpose. He urged that the scholarship should be awarded for merit and should bear no relation to the future career of the student. The choice of medicine could be made after the award, and in no other way would the right kind of medical student be selected. This observation was made in view of the fact that during the last year or two of his school career a student who was known *at that time* to be desirous of entering the medical profession was crammed in a small number of science subjects in order to sit for a university entrance scholarship examination. Thereby his general education was severely restricted; and it is literally true, for instance, that many medical students are not able to write a lucid, grammatically correct answer to a question, although the factual content of the answer may be reasonably accurate. This state of affairs may be largely eliminated by the following means.

The entrance scholarship in its present form should be discontinued. A broad general education of the student should be continued up to the time when application is made for his acceptance by the university as a medical student. The candidate for entry should be required to sit a university entrance examination, which should be set and assessed by the university, and which should be wide in its scope, involving a good general education and not a high standard of knowledge in one or two subjects only. The standard attained in this examination would be taken into account in considering (*a*) whether the boy was fit for entry, and (*b*) whether he should be awarded a "scholarship." (This question of entrance scholarships should be considered by the reader in conjunction with that of "post-entry scholarships," discussed below.) The boy's application for entry might be accompanied by a "recommendation" from his head master, this being based on the character, general standard, and development of the boy throughout his school career. This recommendation would be received, together with all the boy's detailed school reports (including examination assessments), by a university committee, whose personnel should comprise representatives of all faculties, and whose function it would be to determine whether the boy was of sufficient standard for entry, whether he appeared likely to benefit from a university education, and whether his predilections indicated his suitability for acceptance as a medical student. The boy would be interviewed by the committee, which in the above ways could satisfy itself that the candidate for entry had received a sound general education. (These procedures would apply with advantage to all prospective university students, irrespective of their preference for any particular branch of study in the university.)

The Financial Aspect

Let us suppose that such a candidate, having satisfied the full requirements for acceptance as a medical student, is found to be unable to afford the expenses incidental to a medical education. The university committee would report to an appropriate Government Departmental Committee and the boy would be given State aid, the amount being determined by the financial status and commitments of the boy's parents, but, if necessary, the amount should be enough to cover completely the boy's expenses, including living expenses, fees, books, instruments, etc. Such aid being granted, the boy would undertake to repay the "loan" (free of interest) when he begins to earn his living, by means of a percentage (say, 5%) of his *net* annual earnings. Even if he has to repay all the money expended by the State on his behalf it would not be an unduly heavy burden for him to bear. (We must remember in this connexion that were it not for this State aid he would not have been able to enter the medical profession at all.) But the boy should be given opportunities of reducing the amount repayable, by means of "scholarships" awarded during his university course—not as the result of special examinations set for the purpose but based on the results of the ordinary examinations of the medical curriculum. For example, if the boy attained a sufficiently high standard in the First M.B. examination the repayment of that part of the loan pertaining to the period concerned with the course of work for this examination should be cancelled. Similar procedures should be adopted in the case of the subsequent examinations. These "post-entry scholarships" would be a strong incentive to the boy to pursue his studies diligently. The sons of well-to-do parents, of course, even though they may pay for their university education, should be subjected to the same careful selection (and elimination). The award in the *entrance* scholarship should also take the form of cancellation of repayment of a part of the loan. I am of the opinion that by such means as these a considerable improvement in the quality of the general run of medical students could be achieved.

We may observe in this place that students entering the university with a view to becoming school-teachers may receive a grant (not, if certain stipulations are fulfilled, a repayable loan) from the Board of Education to cover expenses incidental to a four-year course of study. The amount of the grant depends on the financial status of the parents and may, if necessary, cover completely all tuition and living expenses. The student is recommended to receive such a grant after interview by a selection committee consisting of members of the academic staff of the university. The only stipulation made by the Board of Education in drawing up the agreement with the student is that he promises to teach in an approved school at the end of his course. If the student after qualifying fails to comply with this obligation and does not furnish "valid reasons" for doing so, he is expected to refund the amount of the grant. A modified form of such a procedure as outlined above should not be unacceptable if it be conceded that a medically qualified person does not play a part of less importance in the State than the school-teacher.

The Anatomical Course

Then, with regard to the adverse influence which the present examination system exerts upon the education of the student, I would illustrate my suggestions by particular reference to my own subject (anatomy), the teaching of which has been the object of so much discussion recently, although like considerations can be recommended in other subjects. It will be generally agreed that the student should possess a sound knowledge of the two basic subjects, anatomy and physiology, before he is required to spend a considerable proportion of his time in clinical study. This does not imply a sharp division between the study of these two subjects and clinical studies, but it does demand that a good working knowledge and understanding of the normal structure and function of the human body should be acquired before the bulk of the student's time is devoted to the investigation of abnormal (sick) human beings. The study of "applied anatomy" and "clinical physiology" should of course be continued throughout the clinical years, and much of these matters should be dealt with by the teaching clinicians in association with the appropriate clinical cases. With regard to anatomy, I believe that the biggest bugbear with which the student has to contend is the present necessity for him to carry in his mind numerous facts —many of which he may have first encountered in the early days of his anatomical course—right up to the time of the professional Second M.B. examination, when he is expected to reply to questions involving the memory of the details of all parts of the body. This state of affairs may be remedied in the following way, and at the same time the "education" of the student can receive greater attention.

Suppose a student dissects an upper limb in the first eight or nine weeks of his course. During that time he should be tested for a *reasonably* detailed knowledge of the structure and "functional anatomy" of that limb, and he should be given to understand that he need not utilize his time in repeated endeavours to memorize those details with a view to carrying them in his mind over a period leading up to a Second M.B. examination at the end of five (or four) terms. It is common experience among teachers of anatomy that a student may "know" individual parts of the body at the time of dissection but cannot carry them in his memory for a prolonged period. The time thus saved from repeated attempts at revision of formerly dissected details is rendered available for the study of those aspects of the subject (e.g., general principles, embryology in its broadest sense, normal radiology, etc.) which enable the student to understand the significance of the structures he is dissecting. I firmly believe it is desirable that a student should become acquainted at least once with the details of the general structure of the body. Even if with the lapse of time he is forgetful or hazy concerning many of the details, he has at the back of his mind the knowledge that such structures exist and can be looked up should the occasion arise. If he does not make this acquaintance he does not know that such-and-such structures even exist, and is thus not aware of his own ignorance. Alongside this consideration it must be borne in mind that the recent developments in anatomical teaching do not form merely factual additions to the student's curriculum but are intended to render easier his understanding of the subject, and they have replaced much that was formerly given prominent attention by teachers of anatomy—e.g., the exact attachments and individual actions of muscles, exact markings on bones, exact attachments of ligaments, detailed unimportant relations of various structures, etc. Alteration of the anatomical course should not merely involve a cutting out of such-and-such structures from the syllabus. Indeed, it would be interesting (and amusing) to ask, say, 50 clinicians, medical and surgical, separately to draw up a list of the structures of the human body which could be omitted from the anatomical course. I am inclined to think that acceptance of the sum-total of their suggestions would necessitate professional anatomists looking for occupation in other walks of life. Conversely, if 50 clinicians were separately asked to draw up a list of what each considered the student of anatomy should be taught, the resultant textbook based on their suggestions would probably far exceed in bulk the ones now commonly employed.

I believe, then, that much of the present difficulty, so far as anatomy is concerned, can be circumvented by examining students at the end of each term of their course on the work done during that term, and abolishing the second professional examination. In this way we could get rid of *the premium at present placed on mere feats of memory*. So far as practical politics are concerned, this would necessitate three visits of the external examiner each year, a practice which is general even under existing arrangements. It is common knowledge among anatomists who have had extensive examining experience in a number of universities that the internal examiner (the local professor of anatomy) keeps record cards on which are entered the details of each student's terminal examination results over a period of four terms. These records are rightly consulted by all the examiners concerned in conducting the professional Second M.B. examination, and I am convinced that such detailed records render the professional examination redundant as a means of assessing whether the student should be allowed to proceed with the next part of his course. I would strongly advocate a retention of the necessity for the student to become acquainted with the general structure and function of the body, and deprecate a ruthless cutting down of the detail to be noted, though not necessarily memorized for long periods. The proper understanding of principles and the illustration of practical applications cannot be at all satisfactory in the absence of an adequate background.

While the above details refer to the subject of anatomy, similar principles might be adapted to other subjects in the medical curriculum, the aim being to reduce the necessity for the performance of feats of memory while not ruthlessly eliminating much essential detail. With regard to pre-clinical and clinical teaching, the pre-clinical teachers (with few exceptions) are full-time teachers who have been appointed to their posts in virtue of their teaching and research experience. For the most part they are capable, thoughtful, progressive teachers, and erect the foundation on which later clinical studies are built. Compared with pre-clinical work, clinical study has more "glamour" in the student's mind, and, in general, students are more eager to learn about clinical than about pre-clinical matters. In spite of this the great majority of clinical teachers are honorary members of the staffs of teaching hospitals, the bulk of whose time and thoughts must of necessity be given to matters other than the instruction of medical students. It is becoming generally appreciated that the present status of clinical teaching would be materially improved by the appointment of an adequate staff of full-time clinical teachers. As in the case of pre-clinical teachers, the best clinical teachers are most likely to be those with research interests, eager to further knowledge and progressive in their teaching methods. It is undoubtedly true that pre-clinical studies are best approached in a scientific manner, while a considerable amount of clinical teaching must, from the nature of the work, be of the type of vocational instruction, though as time progresses and research thrives, more and more clinical study will be capable of scientific approach.

Conclusion

In effect, then, the present communication is an earnest appeal to those who are setting out to modify the medical curriculum to take into account the postulate made here, that a proper choice of student, the abolition of financial obstacles to entry into the medical profession by means of an extensive system of State aid, coupled with a ruthless weeding out of unsatisfactory students early in the course, the appointment of an adequate number of full-time clinical teachers, and modification of the existing examination system, will allow of the formulation of a high-standard curriculum. It will be strongly deprecated by many if the main alterations comprise a hasty general "simplification" of the various subjects, resulting in the degrading of the standard of work to the level of an unsatisfactory person wishing to qualify as a doctor.

Since these matters are prominent in the minds of many at the present time, the main object of this communication is to invite and stimulate comment and criticism on the *principles* here set forth, which of course represent only a few of the numerous questions which must receive consideration.

BIRMINGHAM ACCIDENT HOSPITAL

The second annual report of the Birmingham Accident Hospital and Rehabilitation Centre (which took over the Queen's Hospital building) shows that during the twelve months just upon 20,000 new patients suffering from injuries as a result of accident were treated. There were 91,000 casualty attendances, 2,174 in-patients were admitted, and 8,123 operations, many of them, of course, of a minor character, were performed. The high incidence of accidents in industry was the reason for the decision to establish this special hospital, notwithstanding the difficulties of wartime. These difficulties still remain. The old casualty and out-patient departments of the Queen's were inadequate, and plans were made for their alteration and adaptation at a cost of £20,000, but only slow progress has been made owing to shortage of labour and material. The reconstituted block will provide a reception department containing a separate shock room, three operating theatres, and *x*-ray units, and the out-patient treatment department will include a fracture out-patient suite and soft-tissue dressing and redressing stations. One matter of great concern to the board has been the difficulty of obtaining surgical staff. On the other hand, Birmingham industry has responded well both in money and good will. The hospital has become the centre for industrial medical officers and nurses and will eventually become the centre for industrial first-aid workers. The value of having a bacteriological research unit of the Medical Research Council under Prof. A. A. Miles is obvious, when it is considered that at least 11% of reportable accidents in factories are labelled septic. It is likely that the incidence is much higher than this in a large industrial centre like Birmingham, which contains a great number of small factories without either a nurse or a doctor.

War Neuroses, Morale, and Social Psychology

SIR,—Dr. Ronald Fairbairn's article on the war neuroses (Feb. 13) is to be welcomed as one of the most important contributions recently published on this subject. It is a typical example of the application of the Freudian method, which by bold deductions based on an imaginative understanding of the data sheds a new and brilliant light on the subject, transforming not only our understanding of the problem but also our methods of treatment. Others have recognized the existence of separation-anxiety,[1] and even possibly the dependence of the neurotic, but I have not heretofore seen this characteristic symptom welded into its place in a general theory.

My own experience as a Service M.O., having increasingly impressed me with the infantile dependence of the neurotic, has led me to conclusions similar to those of Dr. Fairbairn. Thus I have emphasized the low morale of the neurotic, as well as his desire to return home. This is recognized by the Forces in their policy of boarding out these patients. The logical (or is it illogical?) extension of this policy is seen in the suggestion that malingerers are neurotic and that even they should be boarded out.[1] That is why I venture to criticize Dr. Fairbairn's thesis, not in its essential feature but for its conclusions. For what do these conclusions come to in the last analysis? To this: that good morale counteracts the tendency to war neurosis produced by infantile dependence; but this infantile dependence itself is the very cause of the weakness of those bonds which constitute good morale. We are thus wandering in a circle, as Dr. Fairbairn recognizes when he jokingly remarks that evangelists not psychotherapists should be in charge of treatment. But what is this circle into which we have been led? The Freudian circle is the family circle.

Emotional development is a development from a state of complete dependence to independence, from no responsibility to responsibility, from absence of freedom to freedom. Freedom is pleasurable, responsibility is painful. The cost of freedom is responsibility—i.e., lack of freedom in relation to other members of the community. But man is a social animal; his sense of freedom and of independence is part of his feeling of one-ness (of identification) with the community. It is not freedom from, but freedom within, the community. In other words, the growth of freedom and of independence takes place by changing the dependence on the family for dependence on the community. But the community in its turn must be dependable: individual freedom depends on the social division of responsibility. The individual can only act responsibly in his own sphere provided the community acts responsibly, or reliably, in the rest. But how reliable is the community? How does it first strike on the developing individual? Its first impact is through the school, and from the present point of view the elementary school is woefully inadequate. (How many of us would consider an elementary school education sufficient for our own children? Yet that is all that about 90% of the population get.) And after school the individual is thrown into an environment in which mass unemployment is prevalent, malnutrition is rife, and ever-increasing insecurity the lot of all. It is not surprising therefore that emotional development from the family to the community is prevented. The stimulus is lacking. Such a development is replaced by a concept in which the community is regarded as a sort of larger family. But the family is only a constituent part of the community, in the same way that a cell is part of the body, and therefore such an attitude is regressive—i.e., neurotic.

The solution is now clear. To increase morale, to treat and prevent war neurosis, we must replace dependence on the family by the feeling of one-ness with the community, by a system of education which gives understanding of the nature and aims of the community and the part the individual has to play in it. Lest this seem mere idealistic talk, I would emphasize that such education is being used as a practical and successful method of treatment of the neuroses in the Services.[2]

---

[1] Good, Rankine (1942). *British Medical Journal*, 2, 359.

[2] Jones, Maxwell (1942). Ibid., p. 276.

For obvious reasons I have compressed my opinions to the minimum space possible. The prevention of war neuroses is of the utmost importance because of its intimate connexion with morale. I hope the matter will receive the widest possible discussion, so that we may be prepared for the problems we shall meet as the war deepens in intensity and widens in range. —I am, etc.,

M. HAMILTON,
Fl Lieut.

Planning for Treatment of Head Injuries

SIR,—May I endorse Dr. Rowland Hill's lucid and well-balanced letter (April 10, p. 457). Those of us who see many cases of head injury in which the patients have returned to civilian employment cannot fail to be struck with the persistence of symptoms, of which headache is only one. These men have, in many instances, no previous history of neurotic disability and there is evidence of previous good personality. The commonly found euphoria in these cases is also a factor which may cloud the issue and affect the diagnosis as made in hospital. On balance the recently published papers appear to be over-optimistic.—I am, etc.,

Roehampton, S W 15 HAROLD PARSONS.

Strategy and Tactics in Research

SIR,—Dr. F. M. R. Walshe is to be congratulated on his article (April 17, p. 467). Our existing research machinery has done a great deal of good work, but there is still far too much waste and misdirection of energy.

Of recent years research has tended to become more and more a matter of work in laboratories and research institutes. Admittedly, there are some types of work which require full-time specialization, but the over-professionalization of research must inevitably admit the type of worker whose work matters less to him than his career, a danger of which Dr. Walshe's warning is timely. The final outcome of certain tendencies which are at present observable might easily be the divorce of research from practical field-work, and in future planning greater attention must be paid to the amateur in research.

The good research worker is a man who retains the logical, persistent, and often naïve curiosity of childhood. He is likely to be found in any sphere of life. Meeting in his daily round of private practice, public medicine, or hospital duties something which arouses his curiosity, he is impelled to ask "why" or "how" and to follow up his question by research. What he needs, and at present lacks, is some means of finding what work, if any, has been done on that particular problem, whether anyone else is at present working on it, what information bearing upon it, either directly or indirectly, is available, and, where necessary, laboratory and statistical assistance in the more technical details of the work. To-day his resources in respect of the first of these depend upon whether he has access to a large library and the time to use it, and the others upon his good or ill fortune in having the right individuals among his acquaintances. At present he may waste months or years on work which has already been done by someone else, or may be compelled to abandon valuable investigations for the lack of some small but valuable item of information which might be available if only he had the means of finding it.

What we need is some central organization to which any worker could apply when he felt impelled to investigate some problem. This organization could advise him as to whether investigation seemed likely to be worth while, put him into touch with other workers on kindred problems, suggest a technique of research, and provide specialized technical assistance if necessary. What it could not do is to provide him with leisure: is it beyond all our wit to devise a means by which a doctor outside the laboratory could be relieved of some part of his routine work to pursue a promising line of investigation? Cannot we also insist that a proportion of our full-time research workers shall be recruited from men and women who have spent some time in private general or special practice, or in public health or industrial work, not merely in a conscious and deliberate attempt to gain a little "experience," but in the honest work of that branch of medicine without ulterior motive? Not a few men find and develop in themselves, while engaged in clinical or administrative medicine, outstanding research ability, yet for obvious reasons cannot in middle life, under our present system, give up what they have and start a research career at the bottom of the ladder.

As Dr. Walshe points out, papers are written and published for a variety of reasons, though the spate of publication is probably less in this country than in some others. Too many still appear because a young man knows that this is the only way in which he can bring his name before the profession, and it is hard to be free from a haunting fear that man may be degraded to the status of an interesting experimental animal which is bred so that aspiring researchers shall have material. In my private Utopia men will be selected for appointment to research posts only after consideration of the papers which they have *not* submitted for publication; only the man who can set high standards for himself and reject the results of hard work because they fall below these standards can be really trusted with that dangerous drug, success.—I am, etc.,

Accrington JOHN D. KERSHAW
Medical Officer of Health

The Calcium Intake in Pregnancy

SIR,—In an account of the meeting of the Scottish Group of the Nutrition Society held at Edinburgh in December, 1942, Dr. H. M. Sinclair is reported to have stated (*Journal*, 1943, **1**, 51) that in pregnancy "supplementary feeding of calcium must not be indulged in lightly since it might prolong pregnancy and harden the foetal skull." I have been unable to trace any work that supports the belief that a high intake of calcium prolongs either pregnancy (the duration of which is not easy to assess) or labour by hardening of the foetal skull. It is in fact desirable that the intake of calcium by the pregnant woman should be high, particularly during the last three months of pregnancy, when two-thirds of the foetal calcium is deposited. There is agreement among reliable authorities (Coons, C. M., *Bull. Okla. agric. exp. Sta.*, 1935, No. 223; Toverud, R. V., and Toverud, G., *Acta paediatr.*, Stockh., 1931, **12**, Suppl. 2; *Bull. Hlth. Org. L. o. N.*, 1938, **7**, 460) that the calcium requirement of the pregnant woman is 1.5 to 2 g. per day, or approximately twice the normal requirement.

Recently at this hospital certain aspects of pregnancy in primiparous women have been studied. The investigation included, among others, observations on two groups of cases, one of which ingested 1 g. and the other approximately 3 g. of calcium daily throughout pregnancy, commencing at the second month. The duration of pregnancy (so far as it is possible to measure this) and labour (first, second, and third stages) was essentially the same in both groups. In the abstract of Dr. H. M. Sinclair's paper the daily dosage of calcium which, it is suggested, might lead to a prolongation of pregnancy and labour (hardening of the foetal skull) was not given. In my preliminary observations cited above the calcium intake in one group was as high as 3 g. daily, a figure not commonly exceeded, and this dosage in no way adversely influenced pregnancy or labour. In pregnancy it would seem wiser to stress the well-established complications resulting from calcium deprivation, rather than the unproven dangers of calcium overdosage.—I am, etc.,

Middlesex Hospital J. DOUGLAS ROBERTSON.

Asthma in Childhood

SIR,—From the articles in the *Journal* of April 3 by Sir Arthur Hurst and Dr. C. H. Rogerson one obtains the impression that both writers have been concerned with established cases of asthma.

The general practitioner has the opportunity of observing children about the age of 3 or 5 suffering from the first, or one of the first, attacks of asthma. At such an early age psychological factors are not of the same importance as in the older child, and the family doctor may obtain the help of the parents, rather than the reverse, in treating the case. The parents can be instructed never to show the slightest sign of alarm should the child have another attack and never to talk of the "wheezy noises" or let the child think there is anything unusual about the breathlessness. Should another attack appear the parents are advised not to send for the doctor, or, if they feel a visit is necessary, not to let the child know the doctor is coming. The child should be spared from sharing in the anxious state of expectancy occasioned by waiting for the doctor.

For some years it has been my habit to examine for acetone in the urine of every child I see suffering from asthma. I was led to do this owing to the extraordinary variety of symptoms shown by children suffering from ketosis. In children under the age of 6 with asthma I have seldom been disappointed, the urine turning a deep purple colour with the sodium nitroprusside test. The most convenient way of carrying out this test is by the method described by Lawrence in his *Diabetic Life*.

Recently during the routine school examination of a boy of 10 I inquired about the attacks of asthma he had had before school age. I saw the boy in his first attack but did not diagnose asthma until he had a second. The urine showed acetone ++. He was given 1/2 teaspoonful of sod. bicarb. three-hourly in glucose and flavoured glucose drinks. The mother stated that the boy had been free from asthma for five years and that she had improved on my simple remedy by giving the child "citralka" whenever he showed the slightest sign of asthma, and the attack was aborted.

A girl from London aged 4 years was on the waiting list of a London hospital and according to the mother was to be admitted in order that skin tests could be carried out. She had a sharp attack of asthma while on holiday in Edinburgh. The urine contained acetone ++. Ephedrine 1/2 gr. and a teaspoonful of "alkagen" granules repeated in two hours, along with glucose drinks, relieved the attack, and after several doses of the alkali the child was free from symptoms. The mother reported from London three months later that the child had been free from asthma except for two threatened attacks which were banished by giving the granules and glucose without ephedrine.

Six similar cases could be quoted; most of them are in youngsters I see from time to time while visiting their homes, and not one has become an asthmatic. In my experience attacks of asthma or acidosis in children under the age of 6 result from dietetic errors or excitement. The common custom of giving young children the "top of the milk," the mother's ration of butter in addition to the child's, along with liberal amounts of cod-liver oil can readily upset the G–FA ratio. In other cases no dietetic error can be found, but the history of a period of excitement, such as a children's party or a boisterous game, may be obtained, and this may have made a heavy demand on the glycogen reserve.

I have not had the same success with children over the age of 8, as usually the attacks of asthma are well established and have become a habit, also the mother–child anxiety link has been firmly joined. There may be ketosis, but curing it does not always banish the asthma. Ultra-violet rays, breathing exercises under the supervision of a competent masseuse, vitamins, and the intelligent co-operation of the parents will do much for the child in danger of becoming an asthmatic.

The late Prof. Gulland used to say the treatment of haematemesis was to give morphia—to the relatives. He might well have included asthma.—I am, etc.,

ALISTAIR G. CRUIKSHANK, F.R.C.P.Ed.,
Temporary Assistant Physician, Royal Infirmary, Edinburgh.

Sulphonamides in Asthma

SIR,—I read with great interest the brilliant survey of the problem of asthma which appeared in your issue of April 3 (p. 403), and I venture to suggest a further hopeful line of treatment which I have been investigating. Sir Arthur Hurst mentioned the importance of bacterial infection of the nasal and bronchial mucous membranes as the primary aetiological factor in some asthmatics. He gives two reasonable suggestions of how such infections may act, to which one may add a third. Is it not possible that the bacteria themselves are the provocative allergen, as indicated by the occasional asthmatic reaction in such patients when given an excessive dose of an autogenous vaccine? No matter which is the more likely interpretation, it appears reasonable to suppose that an intermittent intensive course of one of the sulphonamides would benefit asthmatics who have any chronic, or acute recurring, respiratory infection.

During the last four months I have tried this hypothesis on such cases with apparent success. However, the number of cases, the period of observation, the lack of sufficient controls, and the use of other forms of treatment being sometimes continued by the patients themselves, do not allow me to express any definite opinion at present. I mention it partly to point out a real difference between the aetiology of the average case of asthma as seen in the British Isles and that in North America. Certainly in Canada the incidence of asthmatics with positive skin reactions to various common allergens, and with a history of hypersensitivity to corresponding foods, clothes, or dust, is very high compared with Ireland, where bronchial or nasal infection seems much more common as an exciting cause, and skin tests are often completely negative.

There seems, therefore, good reason in this climate to stress the value of the sulphonamides in asthma, in both prophylaxis and therapy, rather than the use of vaccines. In one patient, a middle-aged man referred for persistent dyspnoea consequent on chronic bronchitis and asthma, the first complete symptomatic relief after three months of constant wheezing was obtained by five days' treatment with sulphathiazole. The vital capacity increased from 1,300 to 2,400 c.cm. in approximately the same period. He had previously tried most of the usual nostrums, including vaccines.—I am, etc.,

Dublin. D. K. O'DONOVAN.

Treatment of Vomiting after Sulphapyridine

SIR,—With reference to Acting Squad. Ldr. R. O. Gillhespy's letter (April 10, p. 459) I am very pleased to confirm the importance of alkalinity of the blood and alkaline excipients in the administration of sulphapyridine. It also materially assists the alkalization process if the liver and bowel are thoroughly prepared with an adequate dose of calomel. This has been my practice in the treatment of almost 300 cases of cerebrospinal meningococcal meningitis, etc., admitted from military and civilian sources during the last seven years.

The almost startling, miraculous improvements in toxic cases of morbilli recently treated in our infectious diseases hospital by this routine have borne out the importance of alkalization in treatment with sulphapyridine. The administration of bicarbonate of soda is pushed until the urine becomes alkaline. The usual symptoms—vomiting, cyanosis, and depression—are reduced to a minimum.—I am, etc.,

G. A. DAWSON,
M.O.H., Darlington.

Blood *p*H and Haemolysis in Blackwater Fever

SIR,—I am indebted to Dr. J. F. Loutit (March 20, p. 360) and Major J. V. Dacie and Col. F. Murgatroyd (April 10, p. 458) for the information contained in their letters on the subject of the recent paper by R. Winstone Evans and me on blood *p*H and haemolysis and its application to the treatment of blackwater fever. I have corresponded privately with Dr. Loutit, but certain of the criticisms raised in the second letter seem to call for an answer, and I hope the following may clarify our position on the clinical side of the question.

The writers object to the assumption that alkalaemia was responsible for the cessation of haemolysis in our cases. We had, however, three facts before us which were independent observations. (1) The marked variations in fragility in any twenty-four-hour period in normal subjects. We could find no factor causing this, but physiological variations in CO_2 content are known to occur, and we suggested these as a possible explanation of the phenomenon. (2) A connexion between *p*H and degree of fragility of red cells was demonstrable *in vitro*. We were not aware that this had been carefully worked out before, as the full literature on the subject was not available to us at the time. (3) A case of blackwater fever had occurred in which tetany, due to ordinary treatment by alkalis, was followed by dramatic clinical improvement and cessation of haemolysis. It seems to me that, knowing this much, it would have been neglectful not to have tried the effect of inducing alkalaemia in suitable cases; and, as stated, our results convinced us subsequently of the therapeutic value of the method. Blackwater fever is sufficiently uncommon and sufficiently dangerous to justify the publication of any reasonable system of treatment if the authors are convinced of its value. Such a system should gain in value if it can be shown to be not purely empirical, and if a theory based on physiological and physical principles and experiments can be adduced to support it. This is what we have attempted to do.

In stating that a combination of jaundice and albuminuria in malignant malaria is an indication for stopping quinine we had particularly in mind cases in which repeated attacks of malaria had occurred within a short period, and in which blackwater fever was, therefore, a likelier complication. The statement was, of course, not intended to mean that treatment should be suspended. We are only too well aware that patients may die of malignant malaria if left untreated, and a special note on the subject of using even quinine courageously is made in discussing a fatal case in the paragraph headed "Factors D and E." Our ordinary practice was to substitute mepacrine for quinine, in cautious doses, in cases where there was any reason to think that blackwater fever might supervene.

Finally, we state only that in our admittedly limited experience we did not find the pre-blackwater state as described in the textbooks. What we did find was a combination of circumstances and symptoms which made us very much on the alert for the appearance of blackwater fever, and these we have described in the article.—I am, etc.,

Felix Smith.

Surgical Emphysema

Sir,—The case described by Dr. Roger Stanley (April 17, p. 477) reminds me of two cases seen by me many years ago when I was a resident at Leicester Royal Infirmary.

A woman who had been knocked about by her husband sustained a fracture of the nasal bones. Whenever she blew her nose in order to get rid of blood, etc., air was blown into the subcutaneous tissues of one side of the face. Gradually the surgical emphysema spread all over the face and neck and thorax. The nose was syringed clear of blood and the patient was advised to refrain from blowing her nose. In a day or two the swelling began to disappear.

A few days later a patient was sent into the infirmary with a widespread surgical emphysema which had come on during labour. Inquiry elicited the fact that the swelling had first appeared on one side of the face. I came to the conclusion that in each case a rent had occurred in the lining probably of the lacrimal duct, and that with every expulsive effort air had been forced from the nostril into the subcutaneous tissues.

Since then, whenever I have come across a case of surgical emphysema I have inquired where the swelling first appeared. In a majority of cases this has not been accurately noticed. But the swelling has begun on "one side of the face" in a number sufficient to convince me that there is no need to presume that a chest lesion is the cause of this condition.—I am, etc.,

Bradford

James Phillips.

Interstitial Emphysema during Labour

Sir,—I have read with great interest the case of interstitial emphysema during labour reported by Dr. Roger Stanley (April 17, p. 477). I attended a rather similar case several years ago.

The patient was a primipara aged 18. She was somewhat anaemic but was otherwise normal. There was nothing exceptional in the medical history. Labour started on a Sunday afternoon and the baby was born at 3 p.m. on the Monday. When the head was distending the vulva the pains became more severe, and light chloroform anaesthesia was induced, and while doing this I noticed that the patient's face was becoming swollen and puffy and giving a sensation of fine crackling crepitus when the hand was passed over it. After expulsion of the placenta there was great swelling of the face and neck as well as of the chest. There was nothing abnormal during the puerperium, and at the end of twelve days all the swelling had disappeared.—I am, etc.,

Dingwall.

J. J. Sinclair.

Diagnostic Test for Kala-azar

Sir,—On coming to this Province as Inspector-General of Civil Hospitals after many years in a specialist appointment elsewhere, I find that the "aldehyde test" for kala-azar originally discovered by me and first described in my note published in the *British Medical Journal*, 1921, **2**, 266, is now everywhere associated not with my name but with another's. The facts are that on finding this remarkable reaction in a small series of cases and realizing its immense usefulness in the diagnosis of an extremely prevalent and disabling disease (easily cured once the diagnosis is made), I wrote describing it not only to you but also to the Calcutta School of Tropical Medicine, where it was abundantly confirmed and allowed to be labelled with another worker's name.

While not disputing the value of subsequent work purely confirmatory in character, I consider I am at least entitled to share the honours. The test is extremely simple and reliable, and is, in fact, performed many thousands of times annually in North-Eastern India in a form not differing in any way from that described by me.

I may perhaps further quote from Major-General Sir Ernest Bradfield's *Indian Medical Review* (p. 206): "In 1921 Spackman introduced for kala-azar a modification of the formol-gel test of Gate and Papacostas, first used for syphilis. The test was further popularized by Napier."—I am, etc.,

Bihar, India.

W. C. Spackman,
Col., I.M.S.

Irritant Spectacle Frames

Sir,—Dr. H. Thistlethwaite (April 17, p. 493) is apparently the first to record in this country the occurrence of sensitization following the wearing of spectacle frames of artificial tortoise-shell. In 1942 I mentioned in a letter to you (Jan. 3, p. 24) that H. S. Berkoff (*Arch. Derm. Syph.*, 1938, **38**, 746) reported a sensitization dermatitis related to the wearing for ten days of spectacle frames of synthetic resin. Berkoff believed that the tricresylphosphate used as plasticizer (non-volatile solvent) in the resin was the irritant agent. It is surely important to ascertain if tricresylphosphate had been used in the present material, and, if so, to test Dr. Thistlethwaite's patients for dermal sensitivity to this substance. Confirmation of Berkoff's results would be an obvious indication for action on the part of the profession in its modern role as guardian of the common man against the products of the synthetic chemist, especially in view of the wide use of artificial resins from babies' toys to suspender clips.—I am, etc.,

Department of Pathology, the University, Glasgow.

A. C. Lendrum.

Sir,—Dr. H. Thistlethwaite (April 17, p. 493) has observed a new form of allergy. Being myself susceptible to this form I noticed that for at least three weeks after buying new spectacles the condition was acute. I at first thought the irritation was due to close-fitting sides or a tight bridge, but it soon became evident that the composition of the frames was to blame, though what precise chemical I am unable to state. There were in the past three years at least ten other cases, but not all the patients bought their spectacles from the same retailer, though I believe that all the frames in this part of the country are supplied by the same manufacturer and are now of the same shape and material.

Treatment in those cases where the spectacles are worn all day consisted in covering the frames—the sides and bridge—with fine darning silk, when the condition improved rapidly. In other cases a 10% solution of ichthammol on lint at night-time proved very effective.—I am, etc.,

J. E. King.

The Services

Temp. Surg. Lieut. J. K. Thomson, R.N.V.R., has been appointed M.B.E. (Military Division) for skill and devotion in tending wounded survivors from a torpedoed merchantman, and Temp. Surg. Lieut. G. J. Laws, R.N.V.R., has been mentioned in dispatches for good services during operations off North Africa.

CASUALTIES IN THE MEDICAL SERVICES

Capt. George Macbeth Calder, R.A.M.C., who was wounded in action in the Middle East in Oct., 1942, died from the effects of his wounds last month. He was the eldest son of Prof. W. M Calder, LL.D., of Edinburgh, and graduated M.B, Ch.B. at Edinburgh University in 1936. After holding hospital appointments in England and Scotland he was specializing in psychiatry under Prof. D. K. Henderson when war broke out.

Flying Officer Harold Patterson Hall, R.A.F.V.R., who was killed in a flying accident on March 12, was born in Oct., 1914, and studied medicine at Newcastle-upon-Tyne, taking the Scottish triple qualification in 1941. After holding a house appointment at a mental hospital he received a commission in the medical branch of the R.A.F. on April 3, 1942, and at the time of his death he was M.O. to a fighter squadron.

Wounded.—Capt. G. O. Brooks, G.M., R.A.M.C., Lieut. H B. Cowan, R.A.M.C., Temp. Col. J. H. Donnelly, R.A.M.C., Major L. H. G. Moore, R.A.M.C.

Obituary

The death occurred on March 15 at Binbrooke, after a long and trying illness, of Dr. WILLIAM J. WILKINSON, a well-known practitioner in North Lincolnshire. He was 65 years of age, and was born and brought up in Lincoln, where his father practised in partnership with the late Dr. Brooke. His mother was a sister of the late Mr. W. H. Battle, the well-known St. Thomas's Hospital surgeon. He did his medical training at St. Thomas's and qualified in 1905. Over thirty years ago Dr. Wilkinson started to practise at Binbrooke, and was M.O.H. to the Louth Rural District Council from 1919 until he retired from the appointment last year. He had been a member of the B.M.A. since 1911, and was chairman of the Lincolnshire Division in 1933–4 and also served on the Executive Committee for some years. Dr. Wilkinson was friend as well as physician to many families, rich and poor, in the scattered country district in which he worked, and no doctor was held in higher regard in the Lincolnshire Wold area. His wife survives him; also a son, Dr. John Wilkinson, who is carrying on the Binbrooke practice.

We regret to record the death last summer at Kyrenia, Cyprus, of Dr. ARTHUR ELDON SCOTT. He studied medicine at the Middlesex Hospital, and after qualifying M.R.C.S., L.R.C.P. in 1896 was resident medical officer at the North-West London Hospital. He served in the last war and afterwards joined the Public Health Service of the Egyptian Government, becoming assistant M.O.H. for Cairo City, and receiving the 4th Class of the Order of Ismail in 1926. Dr. Eldon Scott joined the British Medical Association in 1897, and held office as president of the Cyprus Branch in 1937–8. He was a prominent Freemason.

News has been received of the death on Oct. 15 in Jersey of Mr. ARNOLD SAMUEL FERGUSON, throat, nose, and ear surgeon to the Jersey Dispensary and Infirmary, and aural and ophthalmic surgeon to the Jersey General Hospital. Mr. Ferguson qualified from the Middlesex Hospital in 1893 and obtained the F.R.C.S.Ed. in 1895 after serving as demonstrator of anatomy at the Middlesex Hospital and house-surgeon at the London Throat Hospital and the Oxford Eye Hospital. He was a member of the Anatomical Society and of the Laryngological Section of the Royal Society of Medicine, and joined the British Medical Association in 1893, holding office as chairman of the Jersey Division in 1926–7. He contributed to these columns a number of notes on practical aspects of ophthalmology.

Universities and Colleges

UNIVERSITY OF GLASGOW

A graduation ceremony was held on April 17, when the following medical degrees were conferred:

M.D.—[1]G. H. Bell, [2]W. S. W. Guthrie, [3]G Shearer, A. McPhater.

M.B., CH.B.—J. F. Allan, R. P. R. Allan, A. Armour, Janet Y. Baird, Mary MacN Baird, W. A. Baird, J. Berkeley, J. D. Binning, R. B. Bonar, R. P. Brittain, J. A. M. Broadfoot, H B Brown, R. A. P. Brown, R. J. Calvert, J. Campbell, Margaret M. Chalmers, Isobel J. Cochrane, H. W. Collins, W. Cormack, J. V Coyle, M. C. Crawford, J. T. Cunningham, R. Dallachy, W. H. C. Donald, T. Dougray, J. MacK. Dunn, Louise E Elbert, Elizabeth G. Fenwick, Catherine B. Foster, N. J. Fraser, D J. Gracie, G E Griffiths, W R. Hope, R. A Houston, A. McI. Hyndman, N Hyndman, S E. Jackson, H. F. Jarvie, Anne-Marie Kivlichan, J. Lapraik, E. Leahy, Margaret C. Leitch, A. Lindsay, G. G Lindsay, S. V. Livingstone, W. Lockhart, W. J Logan, M. D. MacAffer, Hope J. B. McAlpine, D. Macdonald, J. H. McDougall, J. McFadden, A. Macfarlane, D McGill, A. R. McGregor, J. J. McGrotty, O. A. MacKenzie, A. H. MacLean, R. D. H. Maxwell, A. W. Mearns, R. M. Mill, J. H Mitchell, D S. Montgomery, J MacI Moore, Anna F. S. Neil, Margaret B C. Orr, Millie M J. Peralta, Muriel H. Reid, C. D. Rigg, J. D P. Robertson, J. R. Rowell, J McG. Shaw, A. Smellie, H. G. Smith, A. Somerville, W. Thorburn, C. Wood, W. Wood, J. P. Young.

[1] With honours. [2] With high commendation. [3] With commendation.

The following prizes among others were awarded:

University Prizes.—Bellahouston Medal: W. F Anderson. Capt. H. S. Ranken, V.C., Memorial Prize: A. R. Currie, G. B S. Roberts (equal). *Special Class Prize.*—Surgery, Macleod Medal: A. G. Melrose.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the requisite examinations, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S.Glas.:

G. W M. Armistead, J Carey, J. Connor, W. B Cowper, J E Dawson, G. T. Donald, T. H. Forrest, B. C. Greenhill, Lore M. Hasslacher-Traub, Barbara V. Hastings, R. E. Heap, Daphne M E Kayton, H. Kraus, F H. Leckie, J. McAllister, J J. McMurray, J. J. MacPherson, R. R. Mahlangeni, D. R. Martin, J E. Miller, H. A Myers, D. Naidoo, Caroline N. Nompozolo, R. M. Oliver, Bridget Purcell, Y D. Sethi, J. M. Stirling, Roza Szteinhaus, N. R. B. Turner.

O. Fehr, a graduate of a recognized foreign university, was also admitted a licentiate.

Medical Notes in Parliament

Comprehensive Health Service Plans

On April 15 Mr. SORENSEN asked Mr. Ernest Brown when his plans for a comprehensive medical and health service were likely to be brought before the House. Mr. BROWN replied that preliminary discussions were taking place with representatives of the medical profession, local authorities, and voluntary hospitals. He contemplated publishing in advance of the introduction of legislation, and, he hoped, in the course of the next two or three months, a general statement of his proposals, which would afford all concerned an opportunity of considering and criticizing them. The plan would not include the mental hospital and mental deficiency services.

Nurses Bill

The second reading of the Nurses Bill was moved in the House of Lords on April 13. This measure has already passed through the House of Commons. Lord SNELL said there was a need for competent assistant nurses who might not reach the qualification set out in the State Register but might be admirable practical nurses when under supervision. Hospitals for chronic patients largely depended on the services of these assistant nurses. Some reports on the nursing profession had proposed that it should be an offence for any person other than a State-registered person or an enrolled assistant nurse to care for the sick habitually for gain, and that had been recommended by the Nursing Reconstruction Committee over which Lord Horder presided, but Mr. Brown felt unable to accept the suggestion.

Lord HORDER said that the nursing profession would welcome the Bill along with the economic adjustments recommended by the Rushcliffe Committee. The two things together would raise the status of the nursing profession in this country. No man or woman who could not be put into the categories of State-registered nurse, assistant nurse, and student nurse should be allowed to attend the sick person. Lord RUSHCLIFFE said that in some local authority institutions 40% of the nursing staff were assistant nurses.

The Bill was read a second time.

Committee on Penicillin

Sir ANDREW DUNCAN reported on April 13 that the first meeting had been held on Oct. 13, 1942, of a committee to report on penicillin. The object of the committee was to secure that all available information regarding clinical and chemical trials and methods of production was collected and exchanged and everything possible done to promote rapid development. The committee included: Prof. A. Fleming, Prof. H. W. Florey, Prof. H. Raistrick, Sir Robert Robinson, Dr. C. R. Harington, Dr. A. N. Drury, Dr. V. D. Allison, Prof. I. M. Heilbron, and Lieut.-Col. Sir Russell Wilkinson, together with representatives of firms engaged in production of penicillin.

Diphtheria and Immunization in Germany

Mr. ERNEST BROWN stated on April 15 that there was no general immunization against diphtheria in Germany, but it appeared to be used locally in epidemics. The much-increased prevalence of the disease in Germany, and the fact that there had been no serious increase in two enemy-occupied countries where immunization was fairly complete, lent support to the British Government's policy in advocating the immunization of children in this country.

Army Education on Venereal Diseases

Answering Mr. Beaumont on April 13 Sir JAMES GRIGG said all officers in medical charge of units had been instructed to give periodical lectures to troops on the subject of venereal disease. Education was a slow process, but he was satisfied with that being made. Notice Board Information No. 28 explained the purpose of Defence Regulation 33B and the action soldiers should take as a result of it. The possibility of issuing films and literature on this subject had not been overlooked, but it was not thought that any at present available would prove effective.

Examination in Services by Women M.O.s

Mr. BELLENGER asked questions about routine examination of men in the Forces by women medical officers. On April 13 Sir JAMES GRIGG replied that soldiers who objected to a complete medical examination by a woman medical officer were not entitled to ask for a male medical officer, but if one were in fact available he would normally carry out the inspection. Women medical officers were usually posted to units or localities where A.T.S. were largely employed. On April 14 Sir **Archibald Sinclair** said R.A.F. personnel could be compelled to undergo routine medical inspection which might be undertaken by a woman medical officer. In practice male medical officers performed these duties save in very exceptional circumstances. On the same day Mr. A. V. **Alexander** said that in the Navy it would be very exceptional for women medical officers to examine personnel other than members of the W.R.N.S. and the nursing services. In an emergency, if a male medical officer were not available, it might be necessary for an officer or rating of the Royal Navy to undergo examination or treatment by a woman medical officer. The Navy had not a large number of women medical officers.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the following infectious diseases were less in incidence than in the previous week by the figures given after each: measles 1,512, scarlet fever 220, pneumonia 204, whooping-cough 124, diphtheria 69.

The only large variations from the totals of the preceding week for diphtheria and pneumonia occurred in Lancashire, where there were respectively 37 and 44 fewer cases. Yorks West Riding recorded the largest drop for whooping-cough, 41 cases. In London and the south-eastern counties scarlet fever tended to rise, though there was a general fall elsewhere.

For the counties the figures given represent the extent of the decline in measles: Durham 284, Essex 202, Lancashire 197, Staffordshire 185, Warwickshire 177, Gloucestershire 173, Hertfordshire 165, Nottinghamshire 123, Devonshire 112, London 107. Increased incidence was recorded in several counties, the largest being Derbyshire 129, Kent 88, Norfolk 84, Surrey 72.

Notifications of dysentery went up by 7 during the week. An outbreak involving 40 persons was reported from Gloucestershire, Cheltenham M.B. Half of the remaining 76 cases were notified in three counties: Yorks West Riding 13, Lancashire 12, and London 11.

In *Scotland* measles was up by 118 cases and whooping-cough by 54, but acute primary pneumonia was down by 60 cases. The higher incidence of measles was due mainly to the epidemic in Glasgow, where notifications rose from 364 to 449. In Edinburgh the cases went up from 139 to 150. The increase in whooping-cough was due to the experience of the same two cities, which recorded increases of 19 and 32 respectively.

In *Eire* another 3 cases of typhus were notified in Co. Leitrim, Carrick-on-Shannon No. 1 R.D. This brings the total cases in this area to 19 in the past three weeks.

In *Northern Ireland* there were 317 cases of measles, compared with 99 in the preceding week: Belfast C.B. 110, and Lisnaskea R.D. 207.

Winter Epidemics

The returns of the fourth war winter now having been completed, it is of interest to compare the experience of the past winter with that of the three preceding ones. The general experience compares favourably with that of the previous war winters. The notifications for 26 weeks—the first 13 of the year and the last 13 of the preceding one—are:

	1939–40	1940–1	1941–2	1942–3
Scarlet fever	30,284	38,647	31,525	61,492
Diphtheria	21,451	31,608	24,992	22,041
Acute pneumonia ..	30,032	29,683	26,800	27,450
Cerebrospinal fever ..	5,432	6,138	3,879	2,176
Dysentery	1,130	2,902	3,671	3,378
Paratyphoid and typhoid fevers	518	637	774	359
Measles	—	370,780	36,132	343,759
Whooping-cough	—	69,403	41,974	37,283
Deaths from influenza in the 126 great towns	4,935	2,554	1,186	1,487

During the past year the incidence of scarlet fever was twice that of the previous winters, but the other infectious diseases common to childhood—diphtheria, measles, and whooping-cough—were at a lower level. The relative position of diphtheria is probably somewhat better than the actual figures suggest, because there has been an increase during the war of the proportion of diagnostic errors. The incidence of paratyphoid and typhoid fevers has been exceptionally light, but dysentery has remained at a high level.

The Week Ending April 17

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,058, whooping-cough 1,944, diphtheria 723, measles 16,732, pneumonia 1,139, cerebrospinal fever 103, poliomyelitis 5, dysentery 107, paratyphoid 3, typhoid 11. The deaths from influenza recorded in the 126 great towns for the week numbered 43.

No. 14

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 10.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

Medical News

Prof. E. D. Adrian, O.M., M.D., F.R.S., will deliver the fifth Sharpey Schafer Memorial Lecture, on "The Sensory Areas of the Brain," on Thursday, May 6, at 5 p.m., in the University New Buildings, Teviot Place, Edinburgh. All interested are invited to attend.

Dr. Karl T. Compton will deliver the Pilgrim Trust Lecture on "The Organization of American Scientists for the War" before the Royal Society, at Burlington House, W., on Thursday, May 6, at 4.30 p.m.

A sessional meeting of the Royal Sanitary Institute will be held at Harrogate on May 15, when papers will be read on "Rheumatism in Relation to Industry" by Dr. S. A. Underwood, and "Treatment Facilities for Rheumatism at Harrogate" by Dr. W. Edgecombe. Dr. R. Sutherland will speak on "Health Education."

The National Council for Maternity and Child Welfare (117, Piccadilly, W.1) has arranged a conference on the conditions of children in the occupied countries of Europe, to be held at the Royal Institution, Albemarle Street, W., on Thursday, May 6, at 2.30 p.m., with Lord Dawson in the chair.

An editorial in the April issue of *Mother and Child* (No. 1, vol. xiv) announces that this journal, founded in 1908 under the title of *National Life*, is now the official organ of the National Baby Welfare Council, with its 47 affiliated societies. The office is at 29, Gordon Square, W.C.1, and the price of each monthly copy is 1s.

Among the new Justices of the Peace for Monmouthshire are Dr. John Henry Verwey and Mr. D. N. Rocyn Jones, M.D., F.R.C.S.Ed.

A medical field service school, to train medical officers serving with United States Army units in the field, has been opened at the American school centre in England.

On April 6 at Grimsby Police Court a woman aged 23 was sentenced to three months' imprisonment, under Defence Regulation 33B, for not complying with the medical officer's notice to be treated for venereal disease. The town clerk said that there was no desire to punish this woman, but the Health Department sought aid in doing something necessary for the well-being of the public.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Nicotinic Acid for Neuralgia

Q.—*Has the treatment of trigeminal neuralgia with nicotinic acid proved to be successful? If so, is it of any value in other forms of neuralgia and neuritis?*

A.—On the supposition that the paroxysms of trigeminal neuralgia are ischaemic in origin, the condition has been treated with vasodilator drugs, including nicotinic acid. In seven cases treated with doses of nicotinic acid ranging from 50 mg. twice daily to 75 mg. four times daily, there was improvement in each instance. But this work awaits confirmation. So far as is known, nicotinic acid has not been used in other cases of neuritis and neuralgia. In the past many forms of treatment have been reported to effect temporary improvement in trigeminal neuralgia, but most of them have subsequently fallen by the wayside. There can be no doubt that structural changes occur in the trigeminal nerve to produce such a sustained and intractable syndrome. Injections of alcohol and division of the sensory root still remain the fundamental treatment

Gonococcal Reinfection and Stricture

Q.—*A patient aged 59 had gonorrhoea at 26. He noticed a gleety discharge in August, 1942. He also has a stricture which only allows the passage of a bougie No. 6 (English). He was treated with sulphadiazine 4 g., lasting for fourteen days on four separate occasions, and the stricture was dilated to No. 13 (English). There is now only the slightest trace of a clear discharge and no heavy threads in the urine, which is normal. Slides showed the gonococcus on the first occasion, but repeated examinations have shown no gonococcus, a very few white cells, and small numbers of Gram-positive diplococci and Gram-negative coliform bacilli. The bacteriologist thinks these are a secondary infection. Is this man infectious?*

A.—Assuming that gonococci were found in August, 1942, this appears to be a reinfection, since a relapse after 33 years is very improbable. The fact that gonococci disappeared rapidly under sulphadiazine therapy, which was more than adequate, suggests that the gonorrhoea is cured and that the patient is non-infectious. The clear discharge is probably due to the stricture and secondary infection. The anterior urethra should be examined with a urethroscope for the presence of follicles, and the prostatic and vesicular secretions by smear and culture; a gonococcal complement-fixation test would be useful. If the results of these are negative it may be assumed that the gonorrhoea is cured; nevertheless, it should be borne in mind that the sulphonamides are less effective when closed foci are present than when there is good drainage, and all tests should be repeated on several occasions. It is important that the stricture should be dilated periodically, up to 16 English; otherwise it is certain to contract.

Pain in the Fore-foot

Q.—*What treatment is recommended for a painful foot resulting from flattening of the metatarsal arch?*

A.—There are numerous causes of pain in the fore-foot. Did it come on after a cross-country run, route march, or P.T.; or insidiously for no apparent reason? Are the toes deformed and painful on movement? Is the patient subject to rheumatism, or has he had a recent infection? Has he lately been convalescent after an accident, operation, or other illness? Are there any callosities? Is the pain localized to any metatarsal head?

All these questions are pertinent. "Flattening of the metatarsal arch" is not a diagnosis. Assuming that the toes are not deformed, that the pain came on insidiously and is localized to the third or fourth metatarsal head, a well-applied pad will give relief. Don't suggest that the patient should buy a pad. They are usually not efficient, and in any case the trouble may be only temporary. A chiropodist will apply a protective pad, and probably in a week or two the pain will disappear spontaneously.

There are not many mechanical conditions of the fore-foot the pain of which cannot be greatly relieved by a good chiropodist. If one or more toes are painful on movement and tender on the dorsum as well as underneath the metatarsal head, physiotherapy, heat massage, and exercises, combined with curtailment of activities for a week or two, is the best treatment. If this is impossible the toe can be worked loose after a hot bath night and morning, and a metatarsal bar applied to the boot will give some measure of rest to the toe. If the pain in the foot synchronized with an infection of some kind, then rest and soothing physiotherapy are essential. There should be no compromise; in the long run time is saved. If it came on after an accident at P.T. or cross-country run, the pain is probably due to bruising or strain, and a protective pad well applied by a good chiropodist is all that is necessary. If the pain has resisted all other treatment a manipulation by an orthopaedic surgeon, followed by physiotherapy, will probably help.

INCOME TAX

Entertainment Expenses

"L. S." is informed that the Commissioners for the Division in which he is assessed have repeatedly ruled on appeal that entertaining expenses cannot be allowed to professional men.

*** We understand that this is a not uncommon view, notwithstanding that such expenditure would be allowed to business men when spent to attract custom. The legal position is governed by Rule 3 (*a*) applicable to Cases I and II, Schedule D, which provides that "any expenses not being money wholly and exclusively laid out or expended for the purposes of the trade or profession" shall not be deducted. On the facts as put by our correspondent this attitude imposes a hardship—i.e., in a case where custom dictates the necessity, or at least the advisability, of affording hospitality solely for reasons of professional gain. The prospects, however, of upsetting such a decision by an appeal to the High Court are not tempting, particularly because, unless the Court holds that there are no grounds on which they could have arrived at their decision, the verdict of the Commissioners on a question of fact is final.

Miscellaneous Queries

D. R.'s inquiries are answered below.

1. No allowance is due for "repayment of a loan"; it is a transaction of a capital nature.

2. A wife's earnings are taxed on the amount of her earnings less one-tenth earned income relief (unless her husband has had the maximum of £150) and less a special allowance of £80. The £165 payable at the reduced rate of tax—i.e., 6s. 6d.—applies to the joint and not to the separate incomes.

3. Whether parents "partially dependent" on a taxpayer create a claim to "dependent relative relief" depends on the circumstances. The parent must be "maintained" by the taxpayer and his (or her) own income must not exceed the statutory limit.

4. The cost of replacing textbooks is admissible in calculating liability under Schedule D, but not where Schedule E applies, as it does in the case of income from an appointment. In neither case is the cost of starting or improving a professional library permissible.

Allowance received for Travelling Expenses

"Z. Y." is a part-time anaesthetist in the E.M.S. and receives a salary of £360 per annum plus £100 per annum for travelling expenses. Is he liable on the £100?

⁂ No, unless the circumstances are such that the £100 includes an amount which is in effect additional remuneration.

LETTERS, NOTES, ETC.

The Oxford Ether Vaporizer

Dr. J. B. H. HOLROYD (Sheffield Royal Infirmary) writes: I fully agree with Dr. Elam's letter (Feb. 20, p. 232) on the Oxford vaporizer; I think this machine is most efficient in every way. I have been using it for several months and my findings are the same as Dr. Elam's. I find that it is very easy to handle and very easy to learn. The students who pass through my hands at the Royal Infirmary are all taught to use it, and, without exception, find no difficulty in getting really proficient. I have tried it on all manner of cases, good risks and bad ones, and get the same satisfactory results. I have never selected the cases, so that I could give the machine a severe trial. A most important finding is that, compared with open ether, a saving of about 60% of ether was obtained in my series of cases and without any complications. I fully endorse Dr. Elam's remark: "the apparatus of choice for the general practitioner anaesthetist."

Histamine for Psoriasis

Dr. E. HAYLING-COLEMAN (Wolverhampton) writes: Some time ago I had an experience somewhat similar to that described by Dr. J. S. Knox (April 3, p. 426). I was treating a case of gastric ulcer with injections of larostidin—i.e., histamine—when to my surprise an old-standing psoriasis rash disappeared. I was so impressed that I looked round for another case of psoriasis to try it on. Again the result was most marked and satisfactory. Unfortunately both are now showing signs of a return of the rash and will need a further course of injections, but the remission has lasted several years.

Age and Perforated Gastric Ulcer

Mr. D. J. P. O'MEARA (Bury St. Edmunds) writes: Dr. Kyle of Brecon reports a case of perforated gastric ulcer in a soldier of 19 years (March 20, p. 370) and remarks that it is unusual at such an age. I have no statistics available, but I thought it might interest him and others to hear of a case of perforated gastric ulcer in a boy of 16 years, who was admitted into the West Suffolk Hospital under my care on June 23, 1941. He was an apprentice engineer, with a history of indigestion for 5 days before admission. Some hours before he was admitted he was seized with acute abdominal pain and vomiting. At operation a small perforated "acute" ulcer was found on the lesser curvature and was repaired. Convalescence was uneventful. Of some interest, too, is a patient of mine, now aged 62, who has had a perforated gastric ulcer on three occasions—in 1927, 1930, and 1935. I did not operate on him in 1927, when he had a gastrojejunostomy performed at the same time. On account of numerous adhesions the last gastric perforation had formed a local abscess before surgical help was requested. Since his last operation, despite a severe attack of pneumonia last year, he has been in fairly good health, with occasional attacks of "indigestion." These attacks are usually accompanied by a call for a visit in case he has "burst again."

Mr. J. R. M. WHIGHAM (St. Andrew's Hospital, E.3) writes: Dr. Kyle will be interested in the article by Lee and Wells, "Perforation *in utero* of a Gastric Ulcer" (*Ann. Surg.*, July, 1923, p. 36). Gastric and duodenal ulcers seem to occur at all ages, and rare instances of perforations in infants and children are to be found in the literature from time to time. My personal experience of cases in patients under 20 consists of two boys aged 17 and 16 respectively, who collapsed at work, with a doubtful period of three weeks' indigestion previously in the case of one of them. Both ulcers were gastric, situated near the pylorus, and at operation simple suturing (with peritoneal drainage in one instance) was successfully performed. The first boy required a gastro-enterostomy two years later (1939) for the recurrence of gastric symptoms, but he has since remained well.

Dr. E. C. EDWARDS writes: Dr. D. Kyle's case prompts me to record an almost similar case which recently came under my care. A healthy-looking young soldier of 20 was admitted to Penzance Hospital suffering from an attack of vomiting with severe abdominal pain, which had developed suddenly three hours before admission and without any previous symptoms. From the history and physical signs I had no difficulty in diagnosing a perforated gastric ulcer and at once performed laparotomy. A perforated small acute gastric ulcer with no surrounding induration was easily found on the anterior surface of the stomach one inch from the pylorus, with a fair amount of stomach contents free in the peritoneal cavity. The perforation was sutured and the patient made an uninterrupted and rapid recovery. The interest of the case seems to lie in the youth and otherwise good health of the patient without any previous symptoms of gastric discomfort.

Infection in the Crowded Surgery

Dr. J. F. PAYAN (Barkingside) writes: It must have occurred to every busy practitioner during these last few weeks how little good we are really imparting to our patients crowded in a stuffy "blacked-out" waiting-room. To see babies in arms inhaling air polluted by bacteria expectorated by the older patients fills me with apprehension. Some of these little creatures may be suffering from some teething disorder, but little do their mothers realize that, before leaving, their babies are already potential sufferers from some more evil complaint. What are we to do? Pressure of work and shortage of petrol preclude doctors from visiting many of these patients at their homes. The ignorant mother wants just advice, which she must obtain after passing through the "lethal" chamber. I wonder that some ingenious person has not devised a mask (not too hideous) for patients to wear when visiting their doctors. How much sickness and unnecessary work would then be prevented?

Training in Preventive Medicine

Dr. S. T. BEGGS (Morecambe) writes: It is contended that a different outlook on medical practice is required in the reorganization of the profession. This can only be brought about in the training of the medical student. Great stress has been placed on preventive medicine both in the Beveridge report and by the Ministry of Health. The student can be directed to this side of medicine only by making the qualification in preventive medicine equal to that in medicine and surgery, so that in a university final the degrees would be bachelor of medicine, bachelor of surgery, bachelor of public health. This should not add greatly to the curriculum except that a six-months attendance would be required at all departments in the public health service of a county borough.

Treatment of Scabies

Dr. R. T. BRAIN writes in reply to Dr. Spackman's letter in the *Journal* of April 17 (p. 496): I was impressed by Dr. Graham's article on scabies treated with one application of benzyl benzoate, which adds support to Mellanby's view that disinfection of the fomites is unnecessary, and it appears to be uneconomic for the local authorities to continue the mass disinfection of patients' clothing. On grounds of hygiene alone I would still advise the thorough washing of sheets and underclothing, as mentioned in my article in the April number of the *Practitioner*, and, moreover, it does eliminate one of the factors, admittedly the least important, accounting for reinfection. I also maintain that although the efficacy of a single treatment given by trained personnel has been demonstrated it would be unwise to depend upon an equivalent standard of efficiency in the home.

Textbooks for Medical Students in Malta

Mr. DAVID PYKE, on behalf of the British Medical Students' Association (B.M.A. House, Tavistock Square, W.C.1), writes: May I appeal to any of your readers who possess unwanted medical textbooks? We have received a letter from the Students' Representative Council of the University of Malta saying that they are desperately short of essential books, mentioning: *Gray's Anatomy, Bigger's Bacteriology, Cushny's Pharmacology, Clark's Applied Pharmacology, Price's Medicine* or *Osler's Medicine, Green's Pathology*, and *Kerr's Obstetrics*. Most of the students at present have no books; the lucky ones have them dating from Lister's time. I believe that before the war students from Malta completed their training abroad, and that the opening of a clinical teaching department, combined with great shortage of shipping space, has produced the present difficult situation. We have been assured of every possible help by the Colonial Office, and therefore anyone who is kind enough to send medical textbooks to us may feel certain that every endeavour will be made to see that they reach our brave friends in Malta.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MAY 8 1943

DESOXYCORTICOSTERONE IN ADDISON'S DISEASE

A COMPARISON OF DIFFERENT METHODS OF ADMINISTRATION

BY

D. M. DUNLOP, M.D., F.R.C.P.Ed.

(From the Clinical Laboratory, the Royal Infirmary, Edinburgh)

It is well established that desoxycorticosterone acetate (D.O.C.A.) is highly effective in the treatment of Addison's disease when given intramuscularly or implanted in pellets under the skin. The drug is ineffective when swallowed. The repeated injection of an oily solution, however, is inconvenient, especially for thin patients with poor muscles, who form the majority of those suffering from Addison's disease; in addition such an injection usually involves a visit to the doctor, and for the uninsured this may add considerably to the already high cost of the drug. The implantation of a big single dose of D.O.C.A. practically eliminates these drawbacks, since such an implantation may suffice for many months. Once implantation has been made, however, there is no means of controlling dosage. Thus dangerous toxic effects such as massive oedema and hypertension are theoretically possible from the excessive absorption of the active principle, and these have been noted by Loeb (1940).

Anderson, Haymaker, and Henderson (1940) reported good results from the sublingual administration of D.O.C.A., comparable to those obtained by injection. Two to six mg. of the drug dissolved in propylene glycol were given daily in divided doses, the drops being retained under the tongue for as long as possible. The D.O.C.A. so administered appeared to be a satisfactory form of replacement therapy for six patients over a period of six to eight weeks. Similar good results were obtained by Turnoff and Rowntree (1941) in two cases. Wilson (1942), on the other hand, found the sublingual use of D.O.C.A. dissolved in propylene glycol of little or no therapeutic value. Despite the daily sublingual administration of as large a dose as 10 mg. the four patients studied showed an alarming tendency to relapse into Addisonian crisis, though they had all previously been maintained satisfactorily by smaller intramuscular doses.

During the last year and a half an investigation has been undertaken into the effectiveness of D.O.C.A. when absorbed from the buccal cavity, and a comparison has been made between its potency when administered in this way and when given by implantation or intramuscular injection. Seven patients suffering from characteristic and unequivocal Addison's disease have been studied.

Criteria of Potency

Some initial difficulty was experienced in determining the clinical criteria to be adopted in assessing the potency of the drug. The mere subjective sensations of the patient were obviously unsatisfactory and unreliable; the blood pressure in Addison's disease often remains low in spite of considerable clinical improvement, and is not an accurate expression of the progress of a case; the blood chemistry is also an inadequate index of the effectiveness of treatment (Dryerre, 1939) since it is often quite normal during the more chronic phases of Addison's disease (Snell, 1934) and it is only at the onset of crisis that significant changes take place in the urea, sodium, and potassium content of the blood (Allott, 1936). D.O.C.A. has, however, such a potent effect in causing retention of sodium that oedema is easily produced even in Addison's disease when it is administered along with salt. The development of oedema may therefore be taken as an indication that the drug is potent, since salt alone in doses up to 15 g. a day will not produce oedema. Even in the absence of actual oedema a steady gain in weight will suggest that the drug is active, especially if the weight falls again when its administration is discontinued.

Sublingual and Sublabial Methods

Fig. 1 shows the effect of the daily sublingual administration of 10 mg. of D.O.C.A. on the weight of two patients suffering from Addison's disease. The drug was dissolved in propylene glycol, and administered by a special dropper under the tongue, being left there without swallowing for 15 minutes. Seven applications of four drops were given each day, equalling a total dosage of 10 mg Throughout the observation 7.5 g. of salt were given daily The ease with which oedema was produced in the first case was due to the fact that the patient had previously been well hydrated by the use of salt and intramuscular D.O C.A.

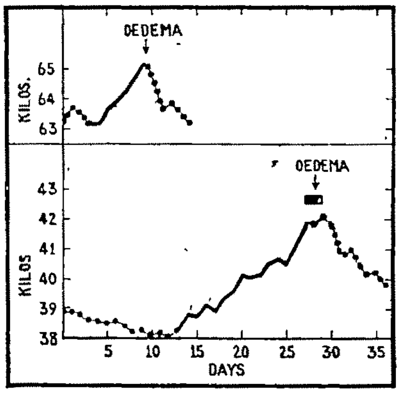

FIG. 1.—Effect of sublingual administration daily of 10 mg of D.O.C.A. dissolved in propylene glycol. The dotted line represents the administration of salt alone; the continuous line represents the administration of salt and D.O.C.A.

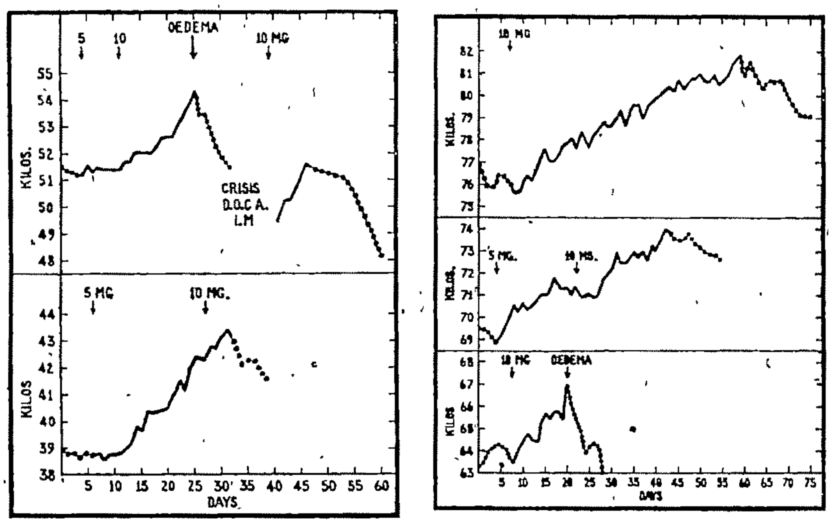
As oedema was produced in both cases these two experiments seemed to prove that D.O.C.A. was successfully absorbed when given sublingually. In propylene glycol the taste of the drug was not objectionable, being like that of the crushed pips of apples, but the method was excessively tedious and laborious. It is true that the smaller doses required for simple maintenance treatment would not have involved so much trouble, but a less cumbersome administrative technique was obviously desirable.

In consequence Organon Ltd. supplied small tablets of D.O.C.A., each containing 2.5 mg. of the drug, which could be held without difficulty between the upper lip and gum for a long time, even after they had begun to crumble. It was hoped that in this situation there would be so little salivary washing of the tablet that any escaping steroid would be absorbed from the oropharynx and pharynx, and that scarcely any would reach the gastric mucosa.

Figs. 2 and 3 represent the effects produced on the weight of five cases of Addison's disease by the drug administered in this way. It will be seen that oedema occurred in only two of the patients. Both of these had received very adequate treatment by intramuscular D O C A. and salt before the experiment began. The other three patients were untreated cases of Addison's disease, starting in a dehydrated state, they had to leave hospital before oedema was produced. In each of these latter cases, however, a significant gain in weight occurred when sublabial D.O.C.A. was given, and weight was lost as soon as it was stopped, in spite of the fact that the daily dosage of 7.5 g. of salt was continuous. Clinical improvement paralleled the gain in weight, and in one case crisis developed when the drug was withdrawn.



FIGS. 2 and 3.—Effect of D.O.C.A. in doses of 5 or 10 mg. daily, administered sublabially in tablets.

These experiments seemed to leave no doubt that D.O.C.A. given in tablets sublabially is effective in the treatment of Addison's disease. Using 2.5 mg. tablets in this way, 10 mg. can easily be administered daily without any of the inconvenience of the sublingual method, and without the disadvantage of making the patient dependent on a doctor or nurse for frequent intramuscular injections of an oily solution.

Deep Subcutaneous Implantation

The late Dr. Henry Dryerre, working in this department, was among the first to observe the effect of D.O.C.A. in Addison's disease when implanted in pellets in the deep subcutaneous tissues. During the past four years we have treated three patients successfully in this way, seven separate implantations having been made. Two of them are in good health. One has died owing to the administration of a general anaesthetic, to which patients with Addison's disease are notoriously intolerant. The implantation of a single dose of 200 mg. of D.O.C.A. kept these patients in good health for periods varying from six to eight months. Subsequent implants then became necessary. The technique is perfectly simple, and no untoward effects, such as those recorded by Loeb, have been produced during the course of seven implantations. It is quite possible that a larger initial implantation—say of 400 mg.—would be safe and would last twice as long as 200 mg., but so far we have not had an opportunity of confirming this possibility.

Comparative Dosage

Owing to the considerable cost of D.O.C.A. it seemed important to ascertain how it could be administered most economically. In one case a comparison has been possible between the minimum dosage required to maintain the patient's weight and to keep him in good clinical condition when the drug was administered by implantation, by intramuscular injection, and by the sublabial method. Similar comparisons have been made in two other cases between two of the techniques —either the implantation and intramuscular or the intramuscular and sublabial methods. The results are shown in the following table:

	Method	Duration in Months	Total Dose in Mg.	Average Requirement per Week in Mg.
Case 1	Implantation	7	200	6·9
		6	200	7·7
	Intramuscular ..	6	240	9·2
	Sublabial	1½	170	28·3
Case 2	Implantation ..	6½	200	7 1
	Intramuscular .	3	120	10 0
Case 3	Intramuscular ..	4	120	7 5
	Sublabial	1	155	38·8

It will be seen that D.O.C.A. is rather more economical when implanted than when injected intramuscularly. It is also more convenient for maintenance purposes, though the intramuscular method should be used in the treatment of Addisonian crisis and in the initial control of an untreated case. Both methods are much more economical than the sublabial technique, which requires from three to five times as much of the drug to produce the same therapeutic effect. It is true that the pharmaceutical packing of the drug in phials or ampoules and the bacteriological sterility tests involved may increase the cost of the parenteral preparations by a few shillings. Such pharmaceutical packing and bacteriological work, however, are relatively so inexpensive in comparison with the cost of the original materials and the chemical processing as to make little difference to the total cost of the final product.

Summary and Conclusions

D.O.C.A. has proved effective in two cases of Addison's disease when administered sublingually dissolved in propylene glycol. The method is very cumbersome and wasteful.

D.O.C.A. has proved effective in five cases of Addison's disease when administered sublabially in tablets. The method is convenient but very wasteful.

Three cases of Addison's disease have been treated by implantations of D.O.C.A. Seven implantations in all have been made, each of 200 mg., without untoward effects. Each implantation has sufficed to keep the patient in good clinical condition for periods varying from six to eight months. It is suggested that implantation is the method of choice on the grounds both of economy and of convenience.

The intramuscular injection of D.O.C.A., though very effective, is rather less economical than its implantation and much more inconvenient. It should be reserved for the initial control of untreated cases and for the treatment of Addisonian crisis.

I am indebted to the Moray Research Fund of Edinburgh University for a grant in aid of the purchase of the D.O.C.A. pellets for implantation, and to Organon Ltd. for supplying the tablets of D.O.C.A. for sublabial use.

Dogs depleted of protein are very susceptible to injurious agents, especially to chloroform. L. L. Miller and G. H. Whipple (*J. exp. Med.*, 1942, **76**, 421) find that methionine administered to dogs shortly before chloroform anaesthesia gives them complete protection against this drug. Similar protection against liver injury is also afforded if methionine—an essential sulphur-containing amino-acid—is given three to four hours after chloroform anaesthesia. They point out that in the past, and often in the present, cases of liver injury are treated with a high carbohydrate diet. Agreeing that there is good reason for this, they state that on the basis of modern work the correct treatment is to give a diet which is high in protein as well.

THE INVESTIGATION OF HAEMOLYTIC TRANSFUSION REACTIONS*

BY

P. L. MOLLISON, M.B., M.R.C.P.

(Concluded from p. 532)

Interpretation of Tests

The large number of tests described above will not all have to be applied in the majority of cases. The procedure should be to test for the most likely cause first and only to apply other tests when the first ones are negative or inconclusive. For instance, preliminary regrouping of the blood of the donor and recipient may reveal a mistake in A–B–O grouping, and in such cases no other tests will be necessary (Cases 1 to 4). Alternatively, if no theoretical incompatibility according to the A–B–O system is revealed between the donor's cells and the recipient's serum, but the recipient is a woman who has given birth to an infant affected with erythroblastosis foetalis, the possibility that the reaction has been caused by previous immunization of the recipient to the Rh agglutinogen should be first considered and the appropriate means taken to test this possibility (Cases 5 and 6).

When a blood sample is taken from the recipient immediately after an incompatible transfusion it should be realized that it may contain an appreciable number of donor cells and that this may possibly lead to a mistaken diagnosis of the recipient's group. Thus, for instance, in Case 4, 24 hours after the transfusion of group B blood to a person of group O the recipient's circulation contained appreciable numbers of B cells, both agglutinated and unagglutinated. In the case of the A–B–O groups mistakes are not likely to be made, however, because the appearance of partial agglutination is so different from the usual complete agglutination of the A and B reactions. In the case of incompatibility due to Rh differences mistakes are more likely, however. When an Rh-negative person already sensitized to the Rh agglutinogen is transfused with Rh-positive cells the post-transfusion sample may contain appreciable numbers of Rh-positive cells although their destruction is proceeding rapidly, and this may lead to the impression that the recipient is Rh-positive (see Diamond, 1942, for instance). The use of powerful sera should enable this appearance of partial agglutination to be recognized with certainty from that of complete agglutination.

When the donor's cells are retested against the recipient's serum it must be remembered that the titre of the offending agglutinin in the latter may be very low after transfusion, so that the donor's cells may appear to be compatible with the recipient's serum. For this reason the pre-transfusion sample of serum from the recipient should be used whenever possible, or else a sample taken at least five days after transfusion.

It must also be borne in mind that in recently delivered women immune agglutinins may be found in the serum owing to stimulation by foetal agglutinogens occurring during pregnancy. There is evidence that when the foetal red cells contain either the A or B agglutinogens and the mother's red cells lack the same agglutinogens, the mother's anti-A or anti-B agglutinins are increased in titre after delivery not only in a proportion of cases (Jonsson, 1936) but in the great majority, reaching a maximum titre 10 to 20 days after delivery (Boorman, Dodd, and Mollison, unpublished observations). In recently delivered women care must therefore be exercised in interpreting the results of serial titrations of agglutinins.

It may be added that agglutinins in the recipient's serum which are not active at 37° C. are in our experience not capable of causing the destruction of transfused red cells.

If stored blood has been used inquiries should be made as to how long it has been stored; inquiries should also be made as to whether the blood was allowed to stand at room temperature for an excessive length of time. The answers to one or other of these questions may suggest the most probable cause for signs of haemolysis following transfusion.

Only when the above causes have been excluded should the possibility that the signs of haemolysis are due to destruction of the recipient's own red cells by high-titre incompatible agglutinins in the recipient's plasma be considered. In such a case, the application of the method of differential agglutination is practically essential in establishing that the signs are not due to destruction of the donor cells, although the agglutinins in the donor's plasma must also be titrated.

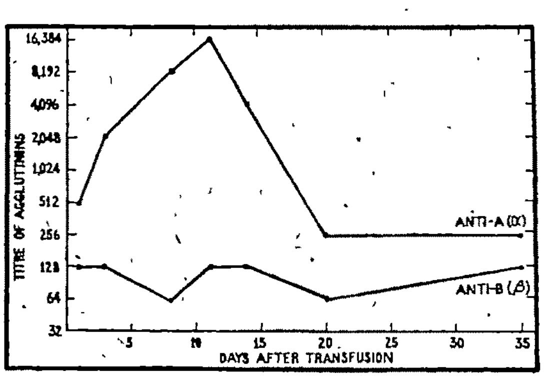
Case Records

The following cases illustrate some of the points referred to in the text and some of the methods of investigation. Cases 1 to 8 illustrate a few of the features of incompatible transfusions. In Cases 1 to 4 blood of incompatible A–B–O group was transfused; in Cases 5 to 8 the blood was of suitable A–B–O group but was Rh-positive and proved incompatible because the recipient had become sensitized to the Rh agglutinogen. In Cases 1 and 2 the early onset of the classical symptoms of severe lumbar pain caused the transfusion to be abandoned after only small amounts of blood had been given. In Case 3, however, an injection of morphine prevented the recurrence of this symptom after its early onset. In Cases 5 and 6 the onset of characteristic symptoms was delayed, and in Cases 4, 7, and 8 no characteristic symptoms developed at any time; in all these cases, therefore, considerable amounts of incompatible blood were transfused. Case 9 illustrates the fact that the occurrence of a rigor does not necessarily indicate incompatibility even when, as in this case, the recipient is Rh-negative and the donor Rh-positive.

In Case 10 the transfusion of grossly haemolysed blood produced the signs of a haemolytic reaction. In Case 11 the transfusion of heavily infected blood gave rise to signs which might have been mistaken for those of a true haemolytic reaction. In Case 12 the possibility of a haemolytic reaction due to incompatibility of the donor erythrocytes was excluded by a cell-survival test.

Case 1: Donor, Group AB; Recipient, Group O.—The patient was a woman aged 60; diagnosis, carcinoma of the colon. Her blood group was determined by the hospital as AB, and a transfusion of group AB blood was begun. No previous direct matching was carried out, owing to a misunderstanding. After a very small amount (about 10 c.cm.) of blood had been transfused she complained of very severe pain in the back. It was assumed that the patient, who had previously received a transfusion of group O blood, had become immunized to the Rh agglutinogen and that the reaction was due to the fact that the donor blood was Rh-positive. The Blood Transfusion Service was therefore asked to supply group AB Rh-negative blood. At this point the patient's blood was submitted for investigation and was found to belong to group O Rh-positive.

Case 2: Donor, Group A; Recipient, Group O.—Woman aged 35; diagnosis, duodenal ulcer with melaena. Blood group determined by hospital as A. Transfusion of group A blood started. Almost immediately after the beginning of the transfusion the patient felt her face "flaming," then she had a very severe throbbing pain in her lumbar region and felt faint. The pain in the back was intense. The transfusion was stopped after 45 c.cm. had been given. Afterwards she shivered for about an hour, and then became very



Graph showing serial titrations of serum iso-agglutinins of a patient of group O who received a transfusion of 45 c.cm. of group A blood (Case 2). The titre is expressed as the reciprocal of the greatest dilution in which agglutination of standard test cells occurred (judged microscopically). In cases in which larger amounts of incompatible blood are given the offending agglutinin is usually found to have a very low titre during the day or two after transfusion.

---

* A report to the Medical Research Council from the S.W. London Blood Supply Depot.

hot and complained of a headache. By the next morning she was perfectly well, but investigations were requested. The recipient's group was found to be O; during the next two weeks the anti-A agglutinin steadily increased in titre, reaching a figure of 16,384, whereas the titre of the anti-B agglutinin remained at 64 to 128 throughout (see Graph). These titrations, as well as the other serum titrations mentioned in this paper, were carried out by Miss K. E. Boorman and Miss B. E. Dodd, to whom my thanks are due for permission to include the results.

Case 3 : Donor, Group A; Recipient, Group O.—A woman aged 30; grouped as A by hospital, transfused with 1,000 c.cm. of group A blood. After receiving 5 c.cm. the patient complained of throbbing in the head and back, and the transfusion was stopped. The symptoms were considered to be neurotic, however, and omnopon gr. 1/3 was injected. The transfusion was restarted, 500 c.cm. being given, without the production of further symptoms, in one and three-quarter hours. At the end of this time the patient developed a rigor, but another 500 c.cm. of blood was transfused during the next 3 hours. At the end of that time a second injection of omnopon was given. The patient slept well, and on waking in the morning had no symptoms. No abnormality of the urine was noted and she did not become jaundiced. The blood urea was estimated on the sixth day after transfusion and found to be normal (30 mg. per 100 c.cm.).

The patient was first seen 9 days after transfusion, not because any suspicion of incompatibility had been aroused, but merely because a request had been received for a further transfusion. Investigations showed that her blood group was O and not A as had been previously believed. Her cells showed no trace of agglutination with a potent anti-A serum—demonstrating (as might have been expected) the complete elimination of the blood given at the first transfusion. Titration of the recipient's iso-agglutinins showed that, whereas the anti-B agglutinin had a titre of 1,000, the anti-A titre was 262,000. Recovery was uneventful.

Case 4 : Donor, Group B; Recipient, Group O.—A woman aged 63, suffering from carcinoma of the lung. Group determined by hospital as B. A transfusion of 600 c.cm. of group B blood was given in 7 hours. Only 250 c.cm. of blood was administered during the first 5 hours, but at the end of this period the patient passed 120 c.cm. of red urine. The transfusion was continued until 600 c.cm. of blood had been given, but investigations were requested in case the passage of red urine had had any untoward significance. Apart from a feeling of hotness towards the end of the transfusion the patient did not develop any symptoms, and considered that she had benefited by the transfusion.

Investigations carried out next day showed that the patient's blood group was O and not B as had been supposed. Examination of a saline suspension of her blood revealed the presence of small scattered agglutinates, the largest consisting of from 8 to 12 cells. These agglutinates could be increased in size by the addition of anti-B serum, showing that besides the agglutinated group B cells there were a number of unagglutinated group B cells remaining in the circulation. As anticipated, the titre of the anti-B agglutinin was found to be very low.

The serum contained 1.3 mg. of bilirubin per 100 c.cm. but no methaemalbumin. (Specimen kindly examined by Mr. R. J. Bromfield.) This latter finding seems important because it is not generally recognized that this pigment may be absent from a sample of the recipient's plasma after the transfusion of a considerable quantity of incompatible blood even when the sample is obtained within 20 hours after transfusion.

A sample of urine obtained 24 hours after transfusion showed no free haemoglobin, but there were a few haemoglobin casts in the centrifuged deposit. The reaction of the urine was acid. The blood urea on the fifth day after transfusion was 35 mg. per 100 c.cm. (after a meal of fish). Death occurred on the sixth day, following signs and symptoms suggestive of pulmonary embolism. Unfortunately permission for necropsy could not be obtained.

Note on Cases 1 to 4.—The grouping mistakes that were responsible for the giving of these four incompatible transfusions were directly due to the use of infected test serum in at least two of the cases; but the fundamental errors in all four cases were the failure to use controls of any kind, presumably owing to over-confidence in the technique used, and the failure to carry out direct matching before transfusion.

Cases 5 to 8 : Donor, Rh-positive; Recipient Rh-negative, Sensitized to the Rh Agglutinogen :

Case 5.—The patient was a woman aged 25 who five days previously had given birth to twins affected with hydrops foetalis. Her group was O Rh-negative, and her serum contained anti-Rh agglutinins. She was transfused with a concentrated cell suspension prepared from the blood of two donors, both of whom were thought at the time to be Rh-negative. In one hour 250 c.cm. of cell suspension was given without the occurrence of any reaction. Shortly afterwards, however, while the transfusion was still running, the patient started to complain of violent lumbar pain, difficulty in breathing, and generalized discomfort. A violent rigor followed. The transfusion was stopped after 300 c.cm. of the suspension had been given. A venous sample was obtained three hours after beginning the transfusion. The serum contained no free haemoglobin but was intensely icteric. The serum bilirubin was found to be 4 mg. per 100 c.cm., compared with the pre-transfusion figure of 0.2 mg. Moreover, the post-transfusion sample of serum gave a "direct" van den Bergh reaction.

Investigations with potent test sera showed that one of the donors was in fact Rh-positive and that all the cells of this donor had been eliminated within three hours of starting transfusion. From the clinical point of view this reaction might well have been considered non-haemolytic, since there was no haemoglobinuria or jaundice.

(Some of the details of this case have been reported previously by Boorman, Dodd, and Mollison.)

Case 6.—(The details of this case are being reported separately elsewhere.) The patient was a woman aged 47. She had had four previous pregnancies, the last 14 years ago. She was admitted to hospital with a diagnosis of menorrhagia. A transfusion of 500 c.cm of group O blood was given. No characteristic symptoms occurred during the transfusion, although a rigor followed it. Next day she was jaundiced, complained of pain in the loins, and passed only 10 oz. of urine. A sample of urine obtained 36 hours after transfusion contained albumin, haemoglobin, bile pigments, and a trace of sugar. Investigations carried out 18 days after the transfusion showed that the patient's group was O Rh-negative and that the donor group was O Rh-positive. Her serum contained moderately strong anti-Rh agglutinins.

The most interesting feature of this case seems to be the persistence of sensitivity to the Rh agglutinogen for at least 14 years, and, moreover, a sensitization of sufficient degree to give rise to a severe haemolytic reaction.

Case 7.—The patient was a woman aged 30 who was given a transfusion of 1,000 c.cm. of group O blood after a severe post-partum haemorrhage. Investigations were requested a week later because the haemoglobin was only 39%. The transfusion itself had been symptomless, and was not followed by jaundice or by any other noteworthy signs. Investigations showed that the patient was group A Rh-negative and that her blood contained a negligible number of group O cells, despite the fact that it was only 7 days since the transfusion. Her serum was found to contain weak anti-Rh agglutinins. The infant's blood was examined for evidence of a haemolytic anaemia, but it appeared to be perfectly normal and the haemoglobin was 120%.

It seems possible that in this case the mother's serum did not actually contain anti-Rh agglutinins at the time of the transfusion but that they were rapidly evoked by the transfusion and that the woman had been sensitized by her pregnancy (the infant was found to be Rh-positive). If this theory is correct this case should not strictly be included, since the definition of haemolytic reactions has been confined here to cases in which destruction starts immediately after transfusion. However, it illustrates well how easily this type of reaction may be overlooked and the features of these reactions merge imperceptibly into those in which destruction starts more rapidly after transfusion.

Case 8.—The patient was a woman who gave birth to her second infant on Aug. 23, 1942. The infant became jaundiced within 24 hours of birth, but a blood count on Aug. 25 showed that its red cell count was 5,320,000 and that its haemoglobin was 105%, so that the diagnosis of haemolytic disease was considered to be excluded. On Aug. 27 a transfusion of 500 c.cm. of a concentrated suspension of red cells prepared from 1,000 c.cm. of group A blood was administered to the mother with a view to correcting a mild secondary anaemia. After transfusion the patient developed a rigor but no other signs or symptoms, and no investigations were carried out at the time.

The infant remained jaundiced, and was seen on Sept. 1. At that time its haemoglobin had fallen to 64% and a diagnosis of haemolytic disease was made. Serological tests showed that the mother was group A Rh-negative and that her serum contained anti-Rh agglutinins. It was noted that no trace of agglutination occurred when the mother's blood was tested with two very potent anti-Rh sera. Since both donors were found to be Rh-positive it was clear that all the donor cells had been eliminated.

Case 9 : Donor, Group O Rh-positive; Recipient, Group O Rh-negative, not apparently Sensitized to the Rh Agglutinogen.—The patient was a woman with three normal children; she was now pregnant for the fourth time and only two weeks from term. Her haemoglobin was found to be 52%, and she was given a transfusion of approximately 750 c.cm. of a concentrated suspension of group O red cells. After the transfusion the patient had a mild rigor, and investigations were requested. These showed that she was group O Rh-negative, but that her blood contained a considerable number of Rh-positive cells, while her serum contained no anti-Rh agglutinins. All four donors who had contributed to the red cell suspension were Rh-positive. A normal infant was delivered two weeks later. One month after the transfusion the patient's blood stream still contained a considerable proportion of Rh-positive cells. It seemed clear, therefore, that the rigor following transfusion was not associated with an abnormal destruction of the donor cells.

Case 10 : Haemolytic Reaction simulated by the Transfusion of Haemolysed Blood.—This patient was an elderly woman with carcinoma of the stomach. It was decided to give a blood transfusion because of her anaemia, and a bottle of a concentrated suspension of red cells was ordered from the Blood Transfusion Service. When the bottle arrived it was placed in the ward refrigerator. A few hours later the doctor arrived to carry out the transfusion and called for this bottle. The probationer went into the room in which the refrigerator was situated, saw a bottle of blood standing on a shelf, and assumed it was the right one. The transfusion of this bottle was completed in two and three-quarter hours, and although no alarming signs or symptoms developed it was noted that the patient was rather flushed and that her temperature had risen to 101° and her pulse rate to 130 to 140. Investigations were requested.

The patient was visited approximately three-quarters of an hour after the end of the transfusion. She was rather flushed and sweaty and had a rapid pulse. The bottle of blood had unfortunately been washed out and only a portion of the label remained. From the data on this portion, however, it was possible to establish that the bottle was seven weeks old. It was then discovered that it had been sent to the hospital after it had already been stored for 19 days in the depot refrigerator, and that it had stood in the ward pantry at room temperature for over four weeks.

A venous sample was obtained from the patient and showed considerable haemoglobinaemia (approximately 100 mg. per 100 c.cm.). Her blood group was A, and differential agglutination showed no trace of surviving group O cells. No urine was passed from the beginning of transfusion until about an hour after the end; then a small amount of highly coloured acid urine was passed. This specimen, however, contained no albumin, no haemoglobin, and no casts. The patient was given large doses of alkali, and the next specimen of urine passed was strongly alkaline. A further venous sample was obtained two hours after the first one. The plasma still contained free haemoglobin, although the degree was less and there was much bilirubin. The patient never became obviously jaundiced, and no further sequelae were noted.

Case 11 : Fatal Reaction due to Transfusion of Infected Blood.—The patient was a woman aged 46 with a history of menorrhagia due to uterine fibroids. As a preparation for operation she was given a transfusion for the relief of her anaemia. Her blood group was O, and the transfusion of two bottles of concentrated cell suspension prepared from group O blood was begun. The transfusion was started at a rapid drip. After one to two minutes the patient said that her face was feeling hot; a few seconds later she complained of generalized discomfort. Her face was found to be very flushed, so the transfusion was stopped after only about 40 c.cm. had been given. The patient next complained of dyspnoea and developed a cough. She said that her head felt as if it were bursting. At this point a venous sample was taken because it was thought that incompatible blood might have been given. Soon afterwards she became worse. She developed abdominal pain and diarrhoea, and then started to shiver. Later she became very collapsed and developed a high pulse and temperature. Her condition deteriorated, and she died 12 hours after the transfusion.

Examination of the donor blood showed that it was grossly haemolysed and heavily infected with bacteria. It is important to note that this haemolysis was revealed only after a mixed sample had been centrifuged. Before transfusion, when the bottles of stored blood were inspected, the supernatant plasma appeared perfectly clear. It is well known that when haemolysis occurs in stored blood the diffusion upwards of haemoglobin into the plasma may only take place slowly. Examination of the venous sample obtained immediately after stopping the transfusion revealed the presence of a small quantity of free haemoglobin in the plasma, which could be accounted for by the amount of free haemoglobin injected.

Case 12 : Incompatibility Excluded by Cell-survival Test.—The patient was a male who had been severely burnt two days previously. He was transfused with 1,000 c.cm. of reputed group O blood. No direct matching was carried out. No donor blood remained for test, and the donors could not be traced. After transfusion the patient had a temperature of 109° F.; he died 10 hours later. A sample of blood was obtained from the body after death and found to be group A. The survival test indicated that there were approximately one million group O cells per c.mm. Thus incompatibility of the donor's cells could be excluded.

Summary and Conclusions

The diagnosis of a haemolytic reaction is based on evidence of increased blood destruction following transfusion and on the demonstration of a cause for this destruction. The commonest causes of severe haemolytic transfusion reactions at the present time are: (1) mistakes in blood grouping; (2) the use of Rh-positive blood for transfusion to recipients sensitized to the Rh agglutinogen; and (3) failure to maintain adequate standards in blood storage.

The investigation of haemolytic transfusion reactions is greatly facilitated if a sample of donor blood is kept available for investigation for at least 24 hours after the transfusion, and is further facilitated if a pre-transfusion sample from the recipient is also kept available for testing. When the patient is seen within 12 or 24 hours of transfusion the increased destruction can often be demonstrated by simply obtaining a venous sample from him and showing that it contains oxyhaemoglobin, methaemalbumin, or an increased concentration of bilirubin. When the patient is seen later the application of the method of differential agglutination is often the only way of demonstrating that the donor's red cells have been rapidly destroyed. Valuable additional evidence can often be obtained by demonstrating the presence of immune agglutinins in the recipient's serum.

It should be possible to diagnose the cause of practically all haemolytic transfusion reactions provided that investigations are initiated within a short time after transfusion, and provided that a sample of the transfusion fluid is available for testing. In practice, however, these conditions are often not fulfilled, and the cause of many haemolytic reactions is therefore never determined. It is considered that the full investigation of these reactions would be one of the most effective ways of raising the standard of blood transfusion.

I should like to thank Dr. J. F. Loutit for helpful criticisms and for kindly allowing me to publish the details of Case 10, which was chiefly investigated by him. I should also like to thank the various medical officers in charge of the other cases investigated for giving me access to their cases and for permission to publish the data reported here.

Under arrangements made by the Ministry of Labour with the governors of Queen Mary's (Roehampton) Hospital the facilities of the latter organization are to be available for the supply of artificial limbs to adults needing them for useful employment. At the same time the Board of Education has given general sanction to education authorities, and the Ministry of Health to welfare authorities, to provide any necessary surgical treatment and artificial limbs for school children. The facilities of Roehampton and of other Ministry of Pensions hospitals are to be at the disposal of local authorities, whose expenditure will rank for grant. This information and the addresses of regional medical officers and of hospitals of the Ministry of Pensions are contained in a circular issued jointly by the Board of Education (No. 1624) and the Ministry of Health (No. 2796).

LEDERLE'S PERTUSSIS ANTIGEN IN TREATMENT OF WHOOPING-COUGH

REPORT OF AN INVESTIGATION

BY

RICHARD S. W. BAKER, M.D., M.R.C.P.I.

Late Assistant Medical Officer, Brook Hospital (L.C.C.), London

In 1940 Joslin and Christensen, having used Lederle's detoxified pertussis antigen in the treatment of a series of cases of whooping-cough, put forward the claim that, if given in sufficient dosage and at suitable intervals, it would shorten the duration of the disease and minimize the incidence of complications.

Methods of Present Experiment

In the investigation here reported there was a total of 20 cases, with an equal number of controls. The cases given antigen treatment were alternate cases admitted during the winter of 1941-2; the remainder constituted the controls. Each patient who received antigen had three injections, given at two-day intervals, consisting of 2 c.cm. of antigen intramuscularly.

The following observations were made in respect of all cases and controls: (1) Duration of stay in hospital. (2) Duration of period in which patient whooped during paroxysms of coughing. (3) Duration of period in which patient was subject to paroxysms of coughing. (4) Blood films made at intervals of 1 to 2 weeks to determine the percentage of lymphocytes. (5) Severity of disease, and complications, if any, noted.

Assessment of Cure.—Obviously it is not easy to determine exactly when a case of pertussis has ceased being so, and in this investigation patients were discharged when a good general condition associated with no coughing, whooping, or vomiting had been established. Nor can one describe the degree of severity of a particular case more accurately than by saying that it is mild, moderate, or severe. For these reasons the preceding observations were made in each case.

Results

The duration of stay in hospital is an approximate indication of the duration of the disease, as in few cases can the actual time of onset be ascertained. Consequently, as most cases were in the paroxysmal stage on admission, it was then that the therapeutic value of the antigen was investigated. The determining of the duration of the period in which the patient whooped during paroxysms of coughing was an attempt to assess the severity of the case, and it is probably true to state that, in general, the sooner whooping ceases the less severe is the attack of pertussis. The duration of the period when the patient had paroxysms of coughing only, constituted a further waning stage of the disease.

In comparing the average length of stay of antigen cases with controls we must consider them in these different respects. It will be seen from Table I that, except for the average duration of stay in hospital, the times of the antigen and control cases correspond quite closely, with the benefit slightly in favour of the latter. This indicates that the antigen did not decrease the time in hospital, nor did it lessen the severity of the disease.

TABLE I.—*Average Duration*

	Cases	
	Antigen	Controls
Stay in hospital	63 days	56 days
Experiencing paroxysms of coughing	58 „	54 „
Whooping during paroxysms of coughing	38 „	37 „

Age Incidence.—Pertussis is confined mainly to children under 5 years of age, and is most serious for those under 1 year. An analysis of the ages of cases in the present investigation provides the figures for Table II.

TABLE II

Age in Years	Number of Cases	
	Antigen	Controls
0–1	0	3
1–2	2	4
2–3	6	7
3–4	4	2
4–5	5	3
5+	3	1

Average age: Antigen cases, 3½ years; control cases, 2½ years.

The numbers in the different age groups correspond fairly well for antigen and control cases, and it is to be noted that the control cases were on the average one year younger. So the age factor does not compensate for the longer duration or the greater severity of the antigen cases.

Severity of Cases.—Cases may be divided roughly into three grades: mild, moderate, and severe. Any case which experiences a spasmodic cough without whooping or vomiting may be classed as mild. The moderate case would have a few whoops superimposed on the spasms of coughing, and the severe case would be liable to attacks of vomiting as well as whooping and coughing. Though patently a very approximate method of assessment, it is of value in showing the distribution and severity of cases, as in Table III. The controls have the greater number of severe cases, which again is of discredit to the antigen.

TABLE III

	Number of Cases	
	Antigen	Controls
Mild	4	2
Moderate	6	4
Severe	10	14

Incidence of Complications.—In this investigation 5 of the antigen and 4 of the control cases developed one or more of the usual complications. Table IV analyses these complications, and of the more serious ones—bronchopneumonia and convulsions—antigen and control cases each had a total of 4. The numbers are too small for it to be said that the use of antigen prevented or minimized the complications.

TABLE IV.—*Type of Complication*

	Number of Cases	
	Antigen	Controls
Bronchopneumonia	4	2
Convulsions	0	2
Diarrhoea	1	3

Lymphocyte Percentage in Blood Films

Differential white blood cell counts were performed at intervals of one or two weeks on all patients, to determine the manner in which the antigen affected the lymphocyte percentage; the results were examined in the following two ways.

In the first method a graph was drawn for each case by plotting lymphocyte percentage against time in days. Should the lymphocyte percentage decrease as the disease wanes, the resulting graph would be a decline. There are two main forms which the graph could otherwise adopt—namely, an incline in the opposite direction and a level trend. Table V analyses the trend of the graphs.

TABLE V.—*Trend of Graph*

	Number of Cases	
	Antigen	Controls
Decline	11	12
Level	1	1
Incline	1	2

The figures are almost identical in both antigen and control cases, showing that the administration of the antigen did not affect the percentage of lymphocytes in the blood. It is to be expected that the lymphocyte percentage would, in a case treated by ordinary methods, approximate to its normal level as the disease diminishes, but Donald (1938) found that relative lymphocytosis persisted even to the ninth week of disease in 50% of cases. This observation would account for those cases which were not in agreement with the "decline" form of graph.

In the second method of examination of the lymphocyte percentage, the average lymphocytosis during the course of the disease was calculated for both antigen and control cases. The figures were 64% for the former and 68% for the latter. Here again no appreciable difference existed between the two groups.

Sauer (1933) and Daughtry-Denmark (1936), as a result of lymphocyte percentage counts taken during prophylaxis of children with pertussis vaccine, found that the figures were raised as in cases of pertussis. The antigen in the present investigation does not appear to have affected the course of the lymphocytosis either quantitatively or qualitatively, and it is reasonable to expect that the former, at least, should have occurred.

Discussion

From the foregoing results it is apparent that the antigen employed as a therapeutic agent in this investigation did not shorten the duration of the disease, render it less severe, or reduce the incidence of complications. Space does not permit a detailed comparison of results with those obtained by Joslin and Christensen, but it may be noted that the dose of antigen we gave was that advocated by them, and the average ages of patients in both experiments are comparable. As those workers did not include the criteria by which they assessed their cures a reliable comparison of the average duration of the two series is not possible. Among their list of complications they included bronchitis, which is not generally accepted as such but is considered an accompaniment of pertussis. By omitting these cases their complication rate can be revised, as follows:

Original percentage :	*Revised percentage :*
Antigen, 0.6% ;	Antigen, 0.4% ;
Control, 18.0%.	Control, 8.0%.

Thus the complication rate of their control cases appears less serious.

In the present investigation 17 out of 20 cases which received antigen were in the paroxysmal stage when admitted. It has been suggested by some workers that vaccines used in the treatment of pertussis must be given in the catarrhal stage to be effective. This remains to be proved for the antigen, and certainly merits attention.

The three cases in the catarrhal stage when injected were in hospital for 76, 60, and 33 days respectively, which figures do not suggest that any amelioration of the disease resulted from use of the antigen.

Summary

Twenty cases of pertussis treated with an antigen are compared with a similar number of controls.

Duration of the disease, complication rate, and lymphocyte percentage were not appreciably affected.

The results of this investigation are briefly compared with those of a similar experiment and discussed.

I wish to acknowledge the permission of the Medical Officer of Health of the London County Council to publish these results, and to thank Chas. F. Thackray Ltd., Leeds, for a generous supply of Lederle's detoxified pertussis antigen.

Sarsaparilla has been used as a remedy for over 300 years, and since the earliest colonial settlement in America it has found favour there as a tonic drink. During the past 50 years there has been an extensive literature on the saponins of sarsaparilla, and according to F. M. Thurmon (*New Engl. J. Med.*, 1942, **227**, 128) only one definite saponin—sarsasaponin—has been isolated from any of the varieties of sarsaparilla. Thurmon has used sarsasaponin in the treatment of psoriasis, and found that it had a beneficial effect on 62% of the 75 patients he treated.

GASTRO-DUODENAL SURGERY IN THE AGED

BY

NORMAN C. TANNER, M.B., F.R.C.S.
Surgeon Specialist to the London County Council, St James Hospital, London

With the ever-increasing progress made—perhaps even more along the lines of pre-operative preparation, anaesthesia, and post-operative care than in actual technique—certain major procedures can now be undertaken at an age which in the past would have been considered prohibitively high. Needless to say, with age and its increased incidence of respiratory infections, cardiovascular degeneration, prostatic obstruction, and so forth, one does not perform major operations without strong indications, but when those indications are present it may be unfair to the patient to make the number of his years the sole factor which denies him the benefits of surgery.

Chronic and frequently relapsing gastric or duodenal ulcers, both of which heal less readily in the aged, and carcinoma of the stomach, or their complications, all form occasional indications for surgery in the later years of life.

Gastro-duodenal Perforation

Acute perforation of peptic ulcer or carcinoma is an absolute indication for surgery. Of 83 such operations performed by me since 1936, 18 were on patients over the age of 60, and 6 over 75. In a series of 5,740 gastro-duodenal perforations taken from the literature by Sandell (1936) only 57 patients were over the age of 60, and the oldest was aged 77. In the same communication Sandell recorded the recovery of a patient of his own, aged 82, after suture of a juxtapyloric perforation.

In my series of 18 patients of 60 and over, two were cases of perforated carcinoma of the stomach. One of these, aged 70, died after simple closure of the perforation; the other, aged 61, made an excellent recovery after an emergency gastrectomy—an operation which seemed advisable because the carcinoma was also causing obstruction. Of the remaining 16 patients with simple perforation three were aged 79 and two 77. One 79-year-old lady with a duodenal perforation of 4½ hours' duration recovered after closure of the perforation under local anaesthesia (this being the second oldest case of perforated ulcer on record to recover). One of the 77-year-old patients also made a good recovery. Of the whole 16 patients with simple perforation 10 died. On closer investigation it becomes apparent that failure to send the patient to the surgeon early, rather than age, was the factor which caused the high mortality. Of the 8 seen and operated on under twelve hours from the time of perforation six made a complete recovery and two died, four weeks and six weeks after operation, from bronchopneumonia and cerebral thrombosis respectively. With such delay the figures could hardly have been much better in youthful patients. It is obviously well worth while to operate on these aged patients if they are presented in reasonably early hours after perforation. No doubt the possibility of peptic perforation does not suggest itself so readily to the practitioner when he is confronted with an aged patient, often with intercurrent ailments and a long history of pain.

Another case—the oldest case of duodenal perforation, and possibly of duodenal ulcer, on record—came to my notice for the first time in the post-mortem room.

A feeble lady aged 91 was admitted to a "chronic ward" on June 8, 1936, complaining of general weakness and occasional lower abdominal pain, with loss of weight. Her abdomen was rather guarded, but presented no other abnormal physical sign. There were pressure sores on the heels and moist crepitations at the bases of both lungs. She became steadily weaker, and had occasional abdominal discomfort until June 17, 1936, when she complained of pain in her chest just before midnight. She collapsed later, and died at 8.15 a.m. the next day.

Post-mortem examination, performed by Dr. Allen B. Bratten, disclosed a general sero-fibrinous peritonitis with two pints of free fluid. On the anterior wall of the duodenum 1.5 cm. beyond the pylorus was an ulcer 1 cm. in diameter, perforated in its centre. Another larger ulcer was present on the posterior wall of the duodenum.

Ante-mortem thrombosis of the left common iliac vein was present, with a recent embolus at the bifurcation of the pulmonary artery and an older adherent thrombus in the left branch. There was generalized arterial atheroma.

Histological examination showed the typical appearance of a chronic duodenal ulcer.

Gastric Carcinoma

Carcinoma of the stomach affords the commonest indication for gastric surgery in the aged. During the past three and a half years I have explored 61 cases of carcinoma of the stomach apart from the two perforated ones described. Of these a radical partial or total gastrectomy was performed in 30, of whom 21 were over the age of 60 and 9 were 70 or over. Of the 9 patients under 60 all but one (a case of palliative total gastrectomy) recovered. Of the 12 between 60 and 70, 10 recovered; and of the 9 over 70, 6 recovered. The 3 over 70 that died were a lady aged 71 who had undergone total gastrectomy (she had carcinoma of 2 cm. of the lower oesophagus and cardia), a patient aged 75 with syphilitic aortitis who had undergone partial gastrectomy, and a man of 70 who developed a cerebral thrombosis.

Among patients whose growths were found irremovable, and on whom only a palliative gastric transection or short-circuit or nothing at all was done, the mortality was higher than in those who had had a gastrectomy—a feature which makes even a palliative gastrectomy justifiable from the patient's point of view.

An 80-year-old partial-gastrectomy patient merits a short note, as he must be one of the oldest patients to survive this operation.

This 80-year-old man was admitted to St. James Hospital on Aug. 5, 1941, complaining of abdominal pain in the evenings, accompanied by vomiting, with anorexia and loss of weight for two months. He was pale and wasted, and had visible gastric peristalsis. Barium-meal radiographs and gastroscopy confirmed the pyloric stenosis, though its actual pathology could not be determined. His condition was improved a little by rest and gastric lavage, though he still had a 48-hours gastric residue of barium. On Sept. 11, under local anaesthesia, a mid-epigastric incision was made. A carcinomatous ulcer of the pyloric canal with infiltration of the right and left gastric and subpyloric glands was discovered, and was treated by radical retrocolic partial gastrectomy—well wide of the tumour and including all the obviously infected glands. Subsequent histological examination showed a trabecular polygonal-celled scirrhous carcinoma of the stomach ("leather-bottle" type). The patient made a good recovery apart from an attack of prostatic obstruction which was treated by suprapubic cystotomy. In Dec., 1942, he still remained active and well, with no sign of recurrent growth.

According to the recent survey of the operations of total gastrectomy by Joll and Adler (1942), the oldest patient to survive this procedure was a man aged 72, recorded by Waugh and Giffin (1941). A description of my successful total gastrectomy for a patient aged 74 may be of interest.

A moderately well nourished man of 74 was admitted to St. James Hospital on Sept. 6, 1942, with a history of two years' periodic mid-epigastric pain two or three hours after meals. His appetite was good. Barium-meal examination on Sept. 8 suggested a duodenal ulcer, and the patient was sent home for three weeks' bed-rest and ulcer diet. On his return he felt much improved and radiography revealed a normal duodenum, but in view of an inconsistent fractional-test-meal curve, which showed a very low free and a high total acidity, I gastroscoped him. An ulcer was revealed, extending from as high as could be seen on the lesser curvature, with a slightly raised and "gelatinous"-looking margin, and a base which appeared to be alternately fibrotic and superficially ulcerated, reminding one of a rodent ulcer. The diagnosis was carcinoma of the superficial spreading type (Stout, 1942).

On Oct. 20, under local anaesthesia, a long mid-epigastric incision was made. A rather flat carcinomatous ulcer was felt on the lesser curvature of the stomach extending as high as the cardia. There were a few hard glands on the upper part of the greater and lesser curvatures. A radical total gastrectomy was performed, removing lesser omentum, right and left gastric vessels and glands, and gastro-epiploic arch. The resection included 2.5 cm. of duodenum and 3 cm of oesophagus. Termino-lateral oesophago-jejunostomy was performed, using two rows of continuous catgut suture, with a few extra stitches from adjacent diaphragmatic peritoneum to jejunum to give support. The long jejunal loop was short-circuited to prevent distension of the duodenum, and a feeding jejunostomy was made. The patient's condition was good, and it remained so throughout the whole post-operative period. Jejunostomy feeds were given from the day of operation, but mouth-feeding was not begun until the fifth day, when the jejunostomy tube was removed. On his discharge on Nov. 21 he could take porridge, an egg, two slices of bread-and-butter, and a cup of tea for breakfast with no discomfort.

Histological examination of the specimen showed a solid acinar polygonal-celled and tubular cuboidal-celled mucous carcinoma of the stomach.

Chronic Peptic Ulceration

In comparison with the frequency with which advanced lesions are found to require surgery in the young and middle-aged, uncomplicated gastric or duodenal ulcers do not often need it at great ages. No doubt this is in part due to the fact that the possession of a chronic peptic ulcer is not conducive to longevity. Of 266 operations personally performed for benign non-perforated ulcer during the last three and a half years, 40 were on patients between the ages of 60 and 76. Generally speaking, with the natural tendency to thinning of the gastric mucosa and diminution of gastric acidity with advancing years, which is accelerated by the retention gastritis associated with duodenal stenosis or pylorospasm and the correspondingly diminished risk of anastomotic ulceration, it is usually safe to perform short-circuiting operations in patients in this age group. Of these 40 operations, 15 were for duodenal ulcer, of which only two were gastrectomies. One other patient, aged 68, had a gastro-jejunal ulcer: this is always best treated by gastrectomy, which was done. The remaining 24 had gastric ulcers, most of them complicated by complete penetration, stenosis, or multiple ulceration; 17 were treated by gastrectomy and 7 by gastro-jejunostomy. Although gastrectomy, after adequate preparation, is the ideal operative solution for gastric ulcer at any age, some of the aged and feeble patients, whose ulcers are associated with marked delay in emptying, may improve greatly in comfort and nutrition after a gastro-jejunostomy.

Of the 20 (aged from 60 to 74) undergoing gastrectomy 17 recovered. Of the 20 (aged from 60 to 76) who had short-circuiting operations 16 recovered. The 7 deaths were due to cerebral thrombosis (1 case), pneumonia (2 cases), anaemic necrosis of colon from caecum to rectum—due to a combination of post-operative colonic distension and atheroma of the mesenteric vessels—(1 case), obstruction from adhesion to the cut end of the ligamentum teres (1 case), and repeated vomiting after anterior gastro-jejunostomy (2 cases).

The mortality from gastro-jejunostomy is high, but it must be remembered that all these lesions were the worst of their type, incompatible with any further span of comfortable existence; nearly all were completely penetrating ulcers associated in most cases with varying degrees of gastric retention in very aged patients, and all had had a very prolonged trial of medical treatment. The anterior gastro-jejunostomies, which were done because of severe destruction and adhesion of the posterior wall of the stomach, gave great anxiety from the tendency to recurrent vomiting, and, though I have occasionally found the operation give an excellent result, on the whole would strongly advise against it. The aged patient will not often stand a convalescence associated with too much vomiting or too prolonged continuous gastric aspiration, which the vomiting necessitates.

Preparation for Operation

The success or failure of a gastro-duodenal operation is largely decided before the patient reaches the operating theatre. It has been demonstrated that there is a direct relation between the prognosis of peptic ulcer operations and the antecedent loss of weight (Studley, 1936).

Patients with an ulcer of such severity as to require surgery often have a background of months or years of undernutrition resulting from fear of pain after food, vomiting, self-inflicted diets, or actual obstruction. On admission they are fatigued and depressed by their latest relapse. They require a preliminary course of feeding on a high-quality diet and rest in bed, partly to increase their resistance to infection and their powers of wound healing (Whipple, 1940), partly to bring the ulcer into as quiescent a stage as possible; also to diminish the gastritis associated with incomplete emptying of the stomach. A high-protein diet diminishes the time-lag before healing of the wound begins (Waugh, 1941). Adequate amounts of ascorbic acid are essential for the formation of collagen fibres and for wound repair (Hunt, 1941). Intravenous saline may be required if dehydration cannot be corrected by the oral route. Bed-rest is essential to produce quiescence of the ulcer and so enable the patient to absorb the food he is given. When there is delay in emptying, daily gastric lavage will often considerably reduce the emptying time, with consequent nutritional improvement.

Anaemia as a result of occult or obvious bleeding from the lesion, or of nutritional deficiencies, is often present, and can usually be corrected by the oral administration of ferrous salts. If this fails, or in the more urgent carcinoma cases, blood transfusion may be required.

The mouth should be cleaned by washes, tooth-cleaning, and scaling—extensive dental extractions should be undertaken only in the more quiescent cases in which there will be time to regain a comfortable and clean mouth well before operation. Breathing and regular limb exercises should be carried out before and after operation. The patient should refrain from smoking for 48 hours before operation.

Prophylactic Sulphapyridine

In May, 1941, I decided to try the use of sulphapyridine by mouth as a prophylactic against pulmonary and peritoneal infection in all gastrectomy cases. The effect was striking. In the 18 months prior to that time there were four fatal primary infections in under a hundred gastrectomies—one case of peritonitis in a completely penetrating ulcer case which was shown at necropsy to have watertight suture lines, two lobar pneumonias, and one confluent bronchopneumonia. In 18 months since then I performed 120 partial gastrectomies for simple ulcer with only one death. These were not selected cases: 6 of the patients had gastro-jejunal ulcers; 20 had multiple ulceration; 42 had complete penetration with the ulcer base in pancreas, liver, or colon; many were stenosed; and their ages ranged up to 74. There were some chest infections in the series, mostly moderate degrees of bronchitis in old bronchitic subjects, and one basal collapse.

Among 14 gastrectomies for carcinoma in the same period there were three deaths—syphilitic aortitis (aged 75), post-operative collapse (aged 68), and leak from a feeding jejunostomy in a total gastrectomy—but none from primary infection. The only severe wound infection occurred in a patient who required colonic resection as well, but he recovered from it. There were a number of minor wound infections.

Anaesthesia

The anaesthetic is of paramount importance. The elderly patient is usually co-operative and not very apprehensive, and forms the ideal type for local anaesthesia. He certainly appears and feels less exhausted after a local than after a deep ether anaesthesia. High spinal anaesthesia is often contraindicated by the presence or suspicion of cardiovascular degeneration. Of all general anaesthetics cyclopropane seems to cause the aged patient the least distress. My preference, however, is for local anaesthesia, and I use either a combination of rectus-sheath block and anterior splanchnic anaesthesia (Braun) or intercostal block with posterior (Kappis) splanchnic anaesthesia. When injecting the splanchnic plexus by the anterior route in the aged care should be taken not to press on an atheromatous aorta or displace it too roughly.

Post-operative Period

For 24 hours after operation the aim is to rest the temporarily paralysed intestine, and so we give by mouth only the little water or fruit juice necessary to enable the patient to take the sulphapyridine comfortably. Fluid is administered by slow rectal drip—tap-water or saline-and-glucose solution. High-quality protein is given in the form of skim-milk, egg, etc., as soon as possible. Boiled sweets to suck or sugar with drinks supply the carbohydrate requirements. Blood transfusion is not given as a routine during or after the operation, though it may be required in rare cases.

Breathing and leg exercises are restarted as soon as the patients recover from their post-operative sleep. When necessary they are instructed to clear their air passages by coughing.

Summary

A case of duodenal ulcer perforation at the age of 91, and cases of recovery from duodenal perforation at 79, from total gastrectomy at 74, and from partial gastrectomy at 80, are recorded.

A series of 120 partial gastrectomies for gastric, duodenal, and gastro-jejunal ulcers with one death is recorded, a result which is attributed in part to the use of prophylactic sulphapyridine.

The causes of death in aged patients after major gastro-duodenal procedures are recorded.

My thanks are due to Dr. W. Allen Daley, Medical Officer of Health to the County of London, and Dr. Norman S Craig, medical superintendent of St. James Hospital, for permission to publish this paper. Dr. E. W. Glennie has given me great help in anaesthetic problems. I must also acknowledge the great nursing skill displayed by Sister B. Dodsworth and Sister M. Ridgeway while these fragile patients were under their care.

INCIDENCE OF PULMONARY TUBERCULOSIS OF ADULT TYPE IN THE R.A.F.

RESULTS OF MASS RADIOGRAPHY OF 75,000 CASES

BY

A. G. EVANS, M.R.C.S., L.R.C.P.

Flight Lieut., R.A.F.V.R.; Assistant Tuberculosis Officer,
Warwickshire and Coventry Joint Committee
for Tuberculosis

The object of this article is to give a detailed analysis of the age incidence and types of case discovered by mass radiography and to discuss the problems which will arise in dealing with these and other cases so discovered in the future. The work of the tuberculosis and health services generally will be considerably increased when mass chest radiology becomes a national undertaking, but it is only by utilizing to the full this recent and valuable addition to our methods of investigation that we can hope to get a real and lasting improvement in the incidence of pulmonary tuberculosis in this country.

As might be expected in a first examination there are wide variations in the extent and degree of activity in the cases discovered, and when running a mass chest *x*-ray unit one is impressed by finding how far advanced some of the active sputum-positive cases have become without any complaint having been made to the medical officer by the airman or airwoman. It may be that to a certain extent a young man who is keen to serve his country conceals his symptoms; but this in itself makes it all the more necessary that men and women in the Services, and the public generally, should have a periodic routine chest *x*-ray examination. It is wishful thinking to expect a majority of early cases at once, before the more advanced cases have been discovered in the preliminary surveys.

Active Cases

Let us first consider the active cases of pulmonary tuberculosis discovered in 75,000 cases, 65,000 of which are airmen

Airmen (65,000) : Unilateral Pulmonary Tuberculosis

	Age Group:	18–19	20–24	25–29	30–34	35–39	40–45	Total
Sputum positive	With symptoms	6	6	2	1	6	1	22
	Without symptoms ..	2	1	2	0	1	0	6
Sputum negative	With symptoms	13	18	1	4	3	1	40
	Without symptoms ..	14	16	1	3	0	0	34

Airmen (65,000) : Bilateral Pulmonary Tuberculosis

	Age Group:	18–19	20–24	25–29	30–34	35–39	40–45	Total
Sputum positive	With symptoms	14	7	2	1	4	2	30
	Without symptoms ..	1	1	1	0	1	0	4
Sputum negative	With symptoms	7	14	3	7	5	1	37
	Without symptoms ..	12	7	1	1	2	0	23

W.A.A.F. (10,000) : Unilateral Pulmonary Tuberculosis

Age Group:		18–19	20–24	25–29	30–34	35–39	40–45	Total
Sputum positive	With symptoms	0	0	0	0	0	0	0
	Without symptoms ..	0	1	0	0	0	0	1
Sputum negative	With symptoms	2	1	0	1	0	0	4
	Without symptoms ..	6	6	0	0	0	0	12

W.A.A.F. (10,000) : Bilateral Pulmonary Tuberculosis

Age Group:		18–19	20–24	25–29	30–34	35–39	40–45	Total
Sputum positive	With symptoms	0	0	0	0	1	0	1
	Without symptoms	1	1	0	0	0	0	2
Sputum negative	With symptoms	3	2	0	0	0	0	5
	Without symptoms	8	4	1	0	0	0	13

and 10,000 of which are W.A.A.F. Our criterion of activity is a strict one, and the patient suspected has a large radiograph, a full clinical examination, blood sedimentation, exercise, and sputum tests, and observation in station sick quarters before such a diagnosis is arrived at. In doubtful cases the film is referred to headquarters for further opinion. The patient is closely questioned as to the presence or absence of symptoms. The accompanying tables analyse the active cases discovered.

From these tables it can be seen that there are altogether 29 unilateral and 37 bilateral sputum-positive cases. Owing to time and present laboratory facilities we have to restrict ourselves to three simple examinations of a sputum smear by the Ziehl-Neelsen method, and on further tests and by concentration methods this would probably be very considerably higher.

In order further to analyse the types of disease discovered by mass radiography, appended below are tables of the radiographs which definitely suggest vomica formation as opposed to infiltration only.

		Airmen	W.A.A.F.	Total
Unilateral	Infiltration only ..	76	11	87
	Infiltration and cavitation ..	26	6	32
Bilateral	Infiltration only ..	67	14	81
	Infiltration and cavitation ..	27	7	34

It is rather alarming to note that 66, or approximately 28%, of these so-called "fit" individuals discovered to have active pulmonary tuberculosis have already reached the stage of cavity formation. Out of these cases 32, or nearly 50%, have returned a positive sputum.

Let us now, for the sake of argument, say that among the active cases all the sputum-positive and all the sputum-negative cases discovered with symptoms will require a sanatorium bed. To start with, this brings us to a total of 152 cases in 75,000, or approximately 2 beds per 1,000 individuals radiographed. It is my opinion that in a mixed civilian population the incidence will be considerably higher, as all people who have entered the Service have been examined and passed by a medical board ; and also, as the civilian sets will probably be distributed in selected industrial areas where the incidence of pulmonary tuberculosis is highest, it will probably work out to more like 3 beds per 1,000.

It is hoped, and anticipated, that a considerable proportion of these cases, having been discovered in an early stage, will be suitable for artificial pneumothorax, which after preliminary induction in a sanatorium can be continued at the local tuberculosis dispensary. By a scheme which will probably be brought in by the Government, at first the patient can be partially re-employed in industry, with compensation for the time that he is unable to work, thereby causing a minimum economic upset to himself or herself and the family as a whole.

Sputum-negative Cases without Symptoms

Let us now consider the unilateral sputum-negative cases without symptoms whose radiographs, clinical signs, and B.S.R. suggest active infiltration without cavitation. Should all these cases be immediately admitted to sanatorium with a view to collapse therapy? The answer is undoubtedly "No." In these cases the patient usually appears to be very fit, and the radiological appearances are probably due to an exudative response to a very small number of bacilli. A somewhat similar appearance can also result transiently from a low-grade apical pneumonia. If, therefore, the patient is under dispensary observation and is radiographed at two-monthly intervals for the first year, no harm should come to him. If at any stage there appears to be extension, then sanatorium treatment should be advised. It is suggested that in the younger age groups so discovered the individual should be re-radiographed six-monthly for two years, then annually for three years. If the patient is then written off the dispensary books he will be given due warning, should any symptoms arise, to report first to his local practitioner.

The bilateral symptomless sputum-negative cases are a debatable problem. It is my opinion that they should, if the bed situation permits, have a preliminary period of sanatorium observation and treatment, particularly with a view to instructing the patient in after-care ; but this will have to be left to the discretion of the local tuberculosis officer.

With regard to the persistently sputum-positive cases it is most necessary that the general practitioner should, from the point of view of public health, continually stress to the patient the necessity for correct disposal of sputum, use of his own eating and drinking utensils and towels, and the like, as it is upon the practitioner who sees the patient weekly or fortnightly that this big responsibility rests. A three- or six-monthly visit to the dispensary does not sufficiently impress the patient, who is inclined to become careless as the years go by. This type of patient should never be re-employed in an indoor industry, however well he may feel in himself, except in a light sedentary clerical job where he has an office to himself. The fact that a patient has become temporarily sputum-negative is no guarantee that he will not again become sputum-positive under conditions of stress. One envisages that in the future there may be some form of industrial segregation of this type of case in the big industrial areas so that they can be usefully employed in indoor industry. It is only by such bold measures that we can hope to tackle efficiently the problems before us.

Inactive Cases

The unilateral and bilateral cases of inactive disease have not been analysed in such detail, but in order to give some idea of the incidence the table below is included. This refers to parenchymatous disease, calcified or fibrotic; including healed Assmann type of foci, but does not include Ghon's foci or calcified hilar glands.

Incidence of Inactive Pulmonary Tuberculosis

	65,000 Airmen	10,000 W.A.A.F	Total
Unilateral ..	248	40	288
Bilateral ..	82	17	99

The majority of these patients are kept as useful members of the Service, in a lowered category, unless the extent of affected lung is such that in spite of the apparent healing it is considered that the airman or airwoman is liable to break down under conditions of stress. A problem that here arises is whether the patient should be told that he has any pulmonary abnormality. It is my opinion that if the disease is unilateral and calcified he should not be told ; but if bilateral, or if there is evidence of infiltration other than calcification, he should be warned to report if any symptoms arise.

A number of these cases may require dispensary observation for a time, and it is a matter for the tuberculosis services to decide what extent of disease will require further observation. Up to the present well under 1% of our cases classed as inactive have broken down since their preliminary radiograph, but as these units have been working for only one year it is rather early to make a dogmatic statement.

Conclusion

I would add that the views expressed are by a medical officer who spent several years as a tuberculosis officer prior to enlistment, and is now fortunate enough to be in charge of a miniature chest radiography unit in the Royal Air Force. My thanks are due to Wing Commander R. R. Trail for his help, and to my colleagues running the other units, without whose co-operation I should have been unable to produce these statistics.

Medical Memoranda

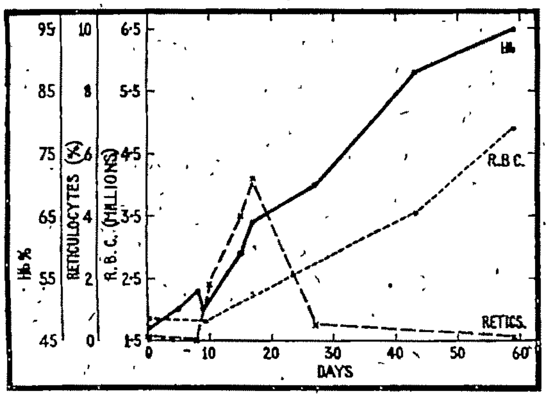
Pernicious Anaemia treated with Pyloro-duodenal Extract and Liver in Tablet Form

Parenteral liver therapy is occasionally complicated by severe reactions. These may take the form of local pain or general effects such as headache, flushing, urticaria, dyspnoea, and even collapse. They are usually overcome by injecting minute doses of liver extract—1/250 c.cm., 1/25 c.cm., and 1/2 c.cm.—at intervals, together with adrenaline. A nervous patient, upset by the reaction, may refuse further injections, and in such a case resort must be had to an oral preparation. An order made by the Minister of Health prohibits the oral use of liver extract as such, but in this preparation the liver is unextracted. It was tested on the following untreated case of pernicious anaemia.

CASE HISTORY

The patient, a woman of 76, was admitted to hospital during an air raid in a state of nervous prostration, her house having been bombed. On recovery she complained of left-sided headaches, which, she stated, had been present for the past six months, occurring in attacks lasting several days at a time. During the last few weeks she had also been subject to fainting attacks. On examination she was found to be a thin pale woman. Her memory was much affected and she had no recollection of her recent misfortune. The right pupil was fixed and irregular, reacting neither to light nor to accommodation. The media of both eyes were opaque. The conjunctivae and mucous membranes of the mouth were pale. Blood pressure was 120/80. The spleen was not palpable, but the splenic dullness was increased. The knee- and ankle-jerks were absent and the calves were more tender than normal. The other systems showed no abnormal physical signs. Blood count: red cells, 1,720,000; Hb, 47%; C.I., 1.38; leucocytes, 2,000—polymorphs 45%, eosinophils 1%, basophils 2%, lymphocytes 48%, monocytes 4%. The red cells were large and showed marked anisocytosis and some poikilocytosis. Reticulocytes amounted to 0.1%. A histamine test meal revealed complete achlorhydria. The patient was given 4 tablets of binaemon three times a day. This was equivalent to a daily dose of 6 g. of fresh liver and 3 g. of fresh pylorus.

Progress.—The effect on the blood picture is shown in the accompanying chart. The reticulocyte crisis did not start till the eighth day, and was small, reaching only 5% maximum, but the rise in the red cell count and in haemoglobin was fairly rapid. By the end of the fourth week the red cell count had risen by 2,000,000, and by the seventh week had reached 4,000,000. This is similar to the recovery rate met with when raw liver is used but slower than that produced by parenteral liver extract, which raises the count to 4,000,000 in about a month. Normal figures were finally reached in the eighth week.



CONCLUSIONS

This preparation of liver and pyloro-duodenal extract in tablet form was found to be effective in treating pernicious anaemia. The difference in cost between this and parenteral treatment is not great. With the latter, assuming that initial doses of extract corresponding to 300 g. of liver are spread over the first 4 days and followed by weekly doses equivalent to 100 g. till the blood count is normal, as recommended by Murphy (1939), the cost of the treatment would be approximately 17s. at hospital prices, as compared with 23s. for the oral method.

My thanks are due to Dr. Allen Daley, Chief Medical Officer to the London County Council, for permission to publish this paper, and to Organon Laboratories Ltd. for supplies of binaemon tablets.

Glandular Fever

The article by Drs. J. Shafar and J. C. R. Weir (*Journal*, Feb. 20, p. 218) on a case of glandular fever with a meningeal reaction raises a number of points of interest at the present moment, when there appears to be an increase in the incidence of infectious mononucleosis. Those authors refer to the general characteristics of their series of some 200 cases. In particular they stress the benign nature of the condition, its marked infectivity, and the unreliability of the Paul-Bunnell reaction. They also state that in differential white cell counts of the blood the polymorphonuclear leucocytes totalled some 50%, and that the remainder was made up of small and large lymphocytes with an average of 10% of monocytes.

During the past few months we have admitted to the County I.D. Hospital here two patients whose cases are fully reported below. These cases closely resemble each other, and were regarded as examples of a clinical entity conforming to the classical description of glandular fever. It will be seen, however, that they differ widely from the cases of Drs. Shafar and Weir in certain important respects. These are: (*a*) The course of the illness was by no means benign. Both patients were sharply ill with intermittent pyrexia, of 14 days' duration, which reached 103.8° F. in one instance and 102.0° F. in the other. (*b*) Infectivity was apparently not pronounced. Both were single cases which occurred separately under Service conditions, and no other cases were reported. Haematological investigation of attendants was not carried out, but none showed any clinical signs of infection. (*c*) The Paul-Bunnell test in both cases was positive in high dilutions. (*d*) The differential white cell counts of the blood showed much higher degrees of mononucleosis, the combined percentages of lymphocytes and monocytes reaching as high as 82. (*e*) There was marked faucial involvement.

It is felt that these considerations help to strengthen the opinion expressed by Drs. Shafar and Weir that there may be "separate and distinct varieties of glandular fever."

CLINICAL HISTORY OF TWO RECENT CASES

Case 1.—A man aged 21 was admitted on July 29, 1942, with a history of headache, shivering, malaise, and abdominal pain of 4 days' duration. On examination he was found to have a temperature of 102.6° F. and a pulse rate of 106. There were no other positive clinical findings, but, in view of his severe headache, lumbar puncture was performed. Clear fluid was obtained, not under pressure, and laboratory investigation showed no departure from normal. A blood count taken on admission gave a total of 5,000 white cells per c.mm. —polymorphonuclear leucocytes 54%, lymphocytes 41%, and monocytes 5%. Blood culture proved negative, and a Widal reaction revealed only slight H-agglutination, which was disregarded as resulting from inoculation. Pyrexia was intermittent, and on Aug. 3 the patient complained of sore throat. He was then found to have a greyish membrane on both tonsils. This separated easily without bleeding, and a throat swab was negative for *Corynebacterium diphtheriae*. Next day non-tender enlarged glands were observed in neck, axillae, and groins, and there was a morbilliform rash on the abdomen. By this time the leucocytes consisted of polymorphs 32.5%, and lymphocytes and monocytes together 67.5%, with a total white cell count of 11,300 per c.mm. The Paul-Bunnell test was positive with a titre of 1 : 896. By Aug. 5 the patient was acutely ill, with a high temperature, rapid pulse, and an extension of the tonsillar membrane and the rash. On this day the white cells numbered 26,000 per c.mm.—polymorphonuclear leucocytes 29%, lymphocytes 22%, and monocytes 49%. He remained very ill for three days and then rapidly improved, with recession of all symptoms. He was discharged well on Sept. 15.

Case 2.—A man aged 22 developed severe headache on Oct. 10, 1942, with nausea and anorexia, and noticed a transient rash, apparently of erythematous type, on both forearms. He reported sick on Oct. 19 and was admitted to sick quarters the same day. He was found to have an irregular pyrexia, reaching on occasion 102° F., and by Oct. 24 he had painless glandular swellings in neck, axillae, and groins. The patient was now admitted to hospital here, and was found to have, in addition, marked faucial congestion, with patches of loose exudate on both tonsils. His blood picture on admission was: polymorphonuclear leucocytes 18%, lymphocytes 70%, and monocytes 12%, with a total white cell count of 16,200 per c.mm. The Paul-Bunnell test was positive with a titre of 1 : 640 Next day he complained of severe headache, and lumbar puncture was performed. The cerebrospinal fluid was normal in all respects On Oct. 29 the tonsillar membrane had extended, and the white cells numbered 15,200—polymorphs 19%, lymphocytes 75%, and monocytes 6%. The pyrexia subsided on Nov. 1, and the patient subsequently improved rapidly. He was discharged well on Nov. 21.

I am indebted to Dr. J. L. Horne, M.O.H., for permission to report these cases, and to Dr. C. C. McCallum, R.M.O., for help in the preparation of the clinical notes.

Reviews

EPILEPSY

Epilepsy and Cerebral Localization. A Study of the Mechanism, Treatment, and Prevention of Epileptic Seizures. By Wilder Penfield, M D, D.Sc., and Theodore C Erickson, M Sc, M D Chapter XIV by Herbert H. Jasper; Chapter XX by M. R Harrower-Erickson. (Pp. 623; illustrated. 44s.) London: Baillière, Tindall and Cox.

In *Epilepsy and Cerebral Localization* Drs. Wilder Penfield and Theodore Erickson set out, as they confess in the preface, to write a book on focal epilepsy. Being struck, however, with the similarity of the mechanisms in cryptogenic and symptomatic epilepsy they were eventually led into a general discussion of the whole problem. The result is a book of somewhat uneven texture. Much of it is of the greatest value, in particular the chapters on functional localization in the cerebral cortex and seizure patterns and their cerebral localization, in which are described numerous observations upon the excitation of fits during operations upon the brain and the correlations noted between such induced attacks and the spontaneous seizures from which the patients had suffered. The production of seizures by surgical lesions of various kinds is fully discussed, and there is a chapter upon the *x*-ray investigation of the epileptic patient. Dr. Herbert Jasper contributes a chapter upon electro-encephalography, expressing the current tendency to find the correlation between the electro-encephalogram and the clinical manifestations of the dysrhythmia a good deal less simple than was at first supposed. The medical aspects of epilepsy are less fully treated than the surgical, and, indeed, probably the day has passed when it was possible for two or even three workers to deal adequately with epilepsy in all its aspects. It would have been better, therefore, if the authors had resisted the temptation to be encyclopaedic. Nevertheless they have earned our gratitude for an outstanding survey of the surgical aspects of epilepsy and a rich mine of data illuminating its clinical features and pathological physiology.

LIFE'S UNFOLDING

Life's Unfolding. By Sir Charles Sherrington, O.M. The Thinker's Library, No. 94 (Science Section). (Pp 124. 2s. 6d) London: Watts and Co.

It was a happy thought on Sir Charles Sherrington's part to reprint in compact form the earlier portion of his Gifford Lectures, dealing with life's unfolding from the synthesis of the protein molecule, through the microscopic cell on to an "organized life system centred upon itself." Here the steps are interpreted by a master of science, enriched with the mind of a philosopher and poet. He reminds us that wonder commonly vanishes with childhood; the wonderful is taken for granted, so as to enable us to get on with life. Later, when life's pace is slackened, wonder may return. Wonder, then, is the mood in which he invites us to approach his subject, and it is indeed a wonderful retelling of the story, both vivid and accurate. One is reminded of a picture, which, having become dulled, is restored to its pristine freshness of colour by a skilful hand. Take, for example, the description of the great adventure by which our marine ancestors adapted themselves to a terrestrial existence, while their descendants still carry about the salt of the archaic sea in their internal economy. Avoiding anthropomorphism in his discussion of "higher" and "lower" forms of life, he still claims that "range of dominance of the environment is a feature to which the term higher can be accorded. Since mind is one of the great keys to this dominance the term is almost graded by degree of mind. At the present time man is as regards conquest of his surroundings the most successful of all living forms. On that ground we can acclaim him the highest."

Sir James Goodhart in his Harveian Oration in 1912, speaking of the passing of the predominance of morbid anatomy, humorously referred to the evolution of the biochemist as a "curious hybrid," and then went on to discuss with sympathetic insight the probable chemical approach to cell physiology and pathology in terms of surface tensions and coenzymes. It has proved almost startlingly prophetic. What he adumbrated, Sir Charles Sherrington here reveals more fully, and asks if deeper knowledge has detracted from the symbolism and pathos of human values. He rightly thinks it would be strange if this were so. To read this book is to understand why the author is secure in the affectionate admiration of all his confrères.

GYNAECOLOGICAL SURGERY

Textbook of Gynaecological Surgery By Sir Comyns Berkeley, M.D., F R C P, F R C.S., and Victor Bonney, M S, M.D., F R.C S. Fourth edition. (Pp. 912; illustrated. 50s.) London, New York, Toronto, and Melbourne: Cassell and Co, 1942.

This is a great book, and its fourth edition will be welcomed. Berkeley and Bonney have individually, and as a brilliant team, made many contributions to surgery, and by outstanding merit have through the years achieved an international reputation of the highest order. Scattered throughout the British Commonwealth of Nations there is a band of younger men whose privilege it has been to serve an apprenticeship at the Chelsea Hospital for Women, London, where they have become imbued with the Berkeley–Bonney tradition. They are the disciples of the Bonney technique and the Bonney conservatism, and to them, as to many others, Bonney is the greatest living exponent of gynaecological surgery. They remember him as an exquisite surgeon, a stimulating thinker and leader, and a rare and generous teacher. To all such men this book is more than a textbook—it is a collection of pleasant memories, brilliantly and lavishly illustrated by graphic sketches drawn by Bonney the artist. The majority of readers will not have shared the privilege of learning technique directly from these distinguished authors, but there can be few who have not been influenced by their teaching and practice. The new edition brings the story of progress in operative gynaecological surgery to date. The sections dealing with vaginal atresia, ovarian operations, and intestinal obstruction have been extensively rewritten, and it is encouraging to note that with greater experience the trend of practice is to become more conservative in the surgery of the pelvis.

A copy of this book should be possessed and studied by all gynaecologists, and by all surgeons who still by obligation or choice occasionally perform these operations. To those who search its pages it will prove itself a guide, philosopher, and friend.

ADVANCED FIRST AID

First Aid: Surgical and Medical By Warren H. Cole, M D., F.A.C S., and Charles B. Puestow, M.S, M D., F.A.C.S. (Pp. 351; illustrated 16s.) New York and London. D. Appleton-Century Company.

It is interesting to read an American book by 19 authors published in 1942 in a country which itself had not up to then seen casualties from air raids in this war. Taken as a whole the volume is well printed, contains numerous illustrations, most of which show well what they are intended to describe, and the subjects dealt with cover a wide area. It is said to be an "advanced guide," and it certainly would appear to give information which can hardly be called "first aid"; as, for example, in dealing with first aid of open complicated fractures of the skull it is stated that "first-aid care involves débridement . . . gross particles of metal, bone, hair, dirt, cloth, head covering, etc., should be removed as well as possible, and the area irrigated with warm, sterile saline solution"! True, it is said that this first aid should be done only by the physician. But is it first aid? Is it not rather surgical treatment to be carried out by a surgeon in hospital?

Chapter I gives an excellent summary of precautions and limitations in first-aid work. In Chapter II general principles are clearly taught. It is questionable whether the short chapter on anatomy and physiology should have any place in a work of this kind. Bandaging is really well illustrated. Blood transfusion is described at far too great a length for a textbook on first aid. The account of the methods of transportation is one of the best extant. Figure 72 gives a graphic description of dangers encountered during an aerial bombardment. The first-aid treatment of abdominal injuries is excellent, and towards the end of the work there is a very good chapter on medical emergencies. The whole book will be read with interest by British workers, although the price is rather high.

Notes on Books

We have received a copy of a useful pamphlet entitled *Insurance for All and Everything* (Longmans, Green and Co.; 1s. 6d.), in which Sir RONALD DAVISON discusses the practical application of Sir William Beveridge's plan for social security—how it might affect the ordinary citizen and how it might be administered. The first part is a summary of the plan, while the second suggests how it would work by taking as an example the life of an imaginary John Smith and Jennie Brown. The author, who says that " Beveridge clearly intends his plan to be an instrument of population policy in these islands," selects the provision of an " all-in medical service " as the most urgent matter arising out of the adoption of a policy of " insurance for all." Of the panel system he says that this " or any wide extension of it could not long carry on . . . it is a meagre and sorry business." This is surely too summary a dismissal of a service which has provided not unsuccessfully for the medical care of a large part of the population for thirty years.

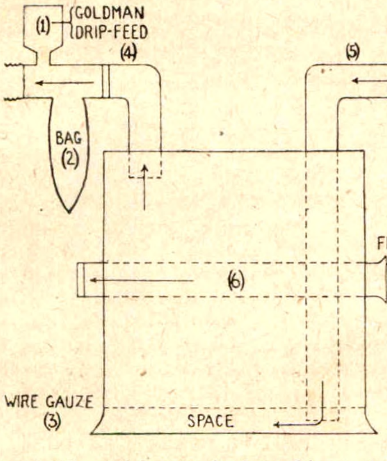
A gentle charm pervades the pages of Dr. E. ROLAND WILLIAMS'S *Jetsam* (W. Collins, Sons and Co.; 1s.), which is a potpourri of memories, scenery, quaint characters, and local superstitions in a setting provided by Welsh hills and the Welsh sea. It is none the worse for a touch of nostalgic sentiment, and a pleasant hour can be spent in reading it.

Preparations and Appliances

CO_2 ABSORBER IMPROVISED AT SEA FROM RESPIRATOR PARTS

Surgeon Commander H. PARRY PRICE (Banbury, Oxon) writes:

Economy in nitrous oxide, oxygen, and ether is of paramount importance in wartime, and more so at sea perhaps than anywhere else. Not so long ago I was compelled to devise a CO_2 absorber from portions of a Service respirator, having to add a McGill rebreathing bag (1) and a Goldman drip-feed for vinesthene (2), which can be equally well used for ether or trichlorethylene (trilene). We overcame the unidirectional valves by borrowing the dental surgeon's 3-way valve from the usual old-fashioned nitrous oxide apparatus, adding a gas inlet on the inspiration side as later described. (This 3-way valve had its expiratory end opened up and tubing attached to it, to lead the expirations back to the absorber.) We overcame the rather costly " cut-out " tap, which would normally cut the absorber out of the circuit, by merely fitting a straight-through pipe on the side of the absorber (6). The tubing (respirator tubing) is detached when one wants to cut out the absorber from joints (4) and (5), and is attached to this straight-through pipe (6). Total rebreathing without absorption is thus obtained. On the other hand the tubing can only be detached at (7), and a cork placed in the metal tube; expiration will then pass out through the end of the tube into the air. This is useful for induction, if one cannot make use of an intravenous barbiturate. A small metal tube is let into the inspiratory end of the N_2O valve to bring in the gases from a Boyle or other apparatus. In our case this was a watersight feed made by our engine-room staff from a Horlick's malted milk pot. It was the only glass jar we could obtain with a metal screw cap. The apparatus gives most efficient results, and I feel certain that it could easily be made at a cost of £3 to £4. Trilene works excellently when used to replace vinesthene in the Goldman drip-feed.



A GAG FOR DYSFUNCTION OF THE TEMPORO-MANDIBULAR JOINT FOLLOWING MANDIBULAR INJURY

Mr. JOHN W. HALLAM, M.R.C.S., L.D.S., writes:

Dysfunction of the temporo-mandibular joint commonly follows upon mandibular injury, although in most cases it is of a very transitory nature. The dysfunction usually manifests itself as a limitation of range of movement, being more marked in a vertical than in a lateral direction. More rarely there is a tendency for the mandible to deviate laterally on opening the mouth.

The causes may be functional, traumatic, or due to wound fibrosis or to actual injury involving the joint. A proportion are induced by the treatment of the injured jaw, the mandible being immobilized in a position contrary to that which it takes when at rest—i.e., with the upper and lower teeth slightly apart; this position of rest is attained with " closed " cap splints. Treatment with open cap splints, interdental, eyelet, arch wiring, or any method which immobilizes the mandible with the teeth in perfect occlusion, is more likely to result in a limitation of mandibular movement.

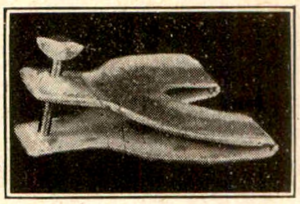


FIG. 1

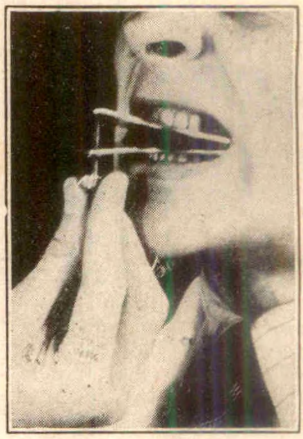

FIG. 2

The functional type is by far the commonest, and is easily recognized by stimulating the glosso-pharyngeal nerve to induce retching. Then, if the patient is shown in a mirror that his capabilities of opening are greater than he imagined, and the mechanism involved is explained to him, a cure will rapidly ensue.

Forcible opening is sometimes necessary in the mechanical types of limitation, the maxillae being separated by means of gags acting between the upper and lower teeth. The gag to be recommended is one which spreads the thrust over the greatest possible number of teeth. This is particularly important when the thrust has to be exerted over an area which has recently been injured (as often occurs). At the Liverpool Jaw Injury Centre such a gag has been devised and constructed which is simple to use and effective in its action (Figs. 1 and 2). In edentulous patients the gag may be covered with black gutta-percha.

A corkscrew, a Mason, or a Ferguson gag produces too great a strain on the two or four teeth against which it operates. The thrust should be maintained for long and regular periods throughout the day. Twenty minutes in every three hours has proved very effective, particularly so when carried out under the supervision and with the encouragement of a dental surgeon. Condylar excision is seldom necessary, and should only be considered when all other lines of treatment have failed.

COMPLETE EXTRACT OF LIVER

There is more than a suspicion that in the purification of the more refined liver extracts for the treatment of pernicious anaemia, factors of value in the treatment of cognate conditions may be omitted. Certainly much of the eluate and filtrate fractions is discarded, though they are known to be of value in experimental anaemias. For this reason the Glaxo Laboratories have prepared a liver extract by a new method in which fractionation procedures are reduced to a minimum, and they recommend it for pernicious anaemia of pregnancy, and the megalocytic anaemias of the nutritional and intestinal type. It is not meant to supplant their " examen " in the treatment of Addison's disease, except perhaps when there are severe spinal lesions. We welcome the product but we cannot but disapprove of the name " plexan," which is even more meaningless and unnecessary than " examen." Surely " complete extract of liver " or (if a Latin name is preferred) " liquor hepatis merus (Glaxo) " would have been more helpful. In spite of protests some British manufacturers remain impervious to the principles of pharmaceutical nomenclature.

PLANNING IN THE TREATMENT OF CANCER

BY

FRANK ELLIS, M.B., M.Sc., F.F.R., D.M.R.
Medical Director, Sheffield Radium Centre

Progress in medicine has mainly been achieved in the past, and will be furthered in the future, by the experimental approach to questions requiring solution. By this is not meant recourse to laboratories and experiments on animals only, important though the part may be which these factors play in elucidating our problems. Mackenzie (1918) stressed the importance of the experimental approach in clinical medicine, and it would seem that the cancer problem might gain considerably by clear-sighted and logical planning of clinical experiments. The implications of the Cancer Act make the planning of such experiments of great importance, and the present state of medical opinion renders them necessary.

The Problem of Radiotherapy or Surgery

Among certain sections of the profession engaged in the treatment of cancer there is a tendency to consider that an issue is at stake; that radiotherapy and surgery are alternatives advocated by their protagonists—an attitude which is tempered only by expediency on the one hand and necessity on the other. Only when an issue is a doubtful one does it provoke a conflict. When doubt is extinguished the conflict ceases. In the treatment of cancer this axiom applies, and the conflict will remain a reflection on the profession and a deterrent to progress unless a conscious effort is made to solve it.

To take one form of cancer considered by most people to-day to be a field for radiotherapy, the answers to certain questions are by no means clear. While the treatment of cancer of the cervix by radiotherapy is generally accepted as better than its treatment by surgery it is by no means proved that in certain selected cases surgical results are not more sure. Though radium treatment is known to result in a certain percentage of cases surviving for 5 years, and although supplementary *x*-ray treatment has been used for several years, it is not proved that the results of the combined treatment show any significant advance. Moreover, while some successes are to be expected from either radium or surgery alone, an inverse proportion of failures is also to be expected. The question thus presents itself: In what proportion of failures by radiotherapy would surgery have been successful, and vice versa?

Furthermore, the question of combined radiotherapy and surgery in this condition is of some importance from the point of view not only of continuing the individual patient's life but also in making that life as free from ill-health as possible. A uterus without cancer may still be better removed. No figures are at present available on this point, although Crossen and Newell (1935) showed that combined surgery and irradiation might be better than irradiation alone.

These problems in connexion with cancer of the cervix may be multiplied in connexion with cancer in any other situation. The aim is at present the best health attainable for every individual patient. It may never be possible to secure this, and with adequate progress in preventive methods and chemotherapy the problem may become archaic before it is solved. This being the common aim, however, for both surgeons and radiotherapists, they should combine to achieve it. The specialization which has become a feature of present-day surgery will provide an impetus to progress because difficulties requiring solution will be realized, methods become more uniform, and interest be more sustained.

The Statistical Approach

The peculiar feature of cancer treatment is that there are so many possible complicating factors that the result in any individual case can be accurately prophesied only in statistical terms. Similarly, the answer to any problem in connexion with cancer treatment must be sought on statistical lines. Suppose the problem is stated in its simplest terms. What Mr. Smith he can treat the patient only once the problem is insoluble. The next best thing would be to treat with radium another patient exactly like Mrs. Brown, having previously operated on Mrs. Brown, and then to observe the results. But it is impossible to keep them under exactly similar conditions for subsequent observation. The only way to solve the problem, therefore, is to treat so many patients with radium and so many with surgery that the differences to be expected between radium and surgical treatment of a single individual will be shown in terms of probability. Statistical methods are such that if large enough groups are chosen and only one factor is varied, an unequivocal statement of the relative effect of the varied factor can be made together with its probable error.

Necessary Measures

To answer the many questions that radiotherapists and surgeons can ask in connexion with cancer treatment, therefore, the following steps are necessary—having in view that the aim is to decide on the treatment in individual cases when the problems have been solved: (1) They must co-operate to decide on *a priori* grounds and in the light of available evidence what are the problems requiring solution. (2) They must devise suitable experiments for each problem. (3) Each experiment must be carried out without variation in the conditions until a statistically certain result is achieved or the problem ceases to require solution because of developments on other lines, such as chemotherapy.

In an experiment it must be ensured that: (*a*) no selection of cases occurs; (*b*) no change in methods of treatment is permitted; (*c*) no other factors are introduced; (*d*) enough cases are treated to discover if there is a statistically significant difference in end-results; (*e*) cases are followed up and observed long enough to justify conclusions being drawn; (*f*) adequate records for the purpose of the experiment are kept.

For instance, it may be decided to determine whether *x* rays alone, contact *x* rays after removal of the thyroid cartilage, or surgical removal by laryngofissure is the best method of treatment for intrinsic carcinoma of the larynx. The best way to avoid selection of cases is to ensure that for the purpose of the experiment only those which are suitable for treatment by any of the methods are included in the groups. Cases considered unsuitable, say, for laryngofissure would be excluded; but they could be included in another experiment —e.g., for determining the better of two radiotherapy techniques.

If the methods decided upon are then followed without variation and the results assessed statistically from time to time, an answer will certainly be obtained. The impending organization of radiotherapy into large centres together with regionalization of surgery will facilitate co-operation and ensure uniformity of method. This co-operation will destroy the antagonism between radiotherapists and surgeons and result in an alliance against cancer.

In this way plans can be made for dealing with all types of cancer so as eventually to know what must be done in any individual case to obtain the best result.

THE TOWN CHILD: A CRITICAL SURVEY

The lessons of the great social experiment of evacuation will take a long time to learn. They will be reflected, we hope, in future housing policy and especially in a new outlook on education. Evacuation threw a grim light on some aspects of town life never dreamed of by those whose acquaintance was only with the exterior aspect of the slums. No sooner had the children been bundled off to their country hosts at the beginning of the war than an outcry arose that many of them were dirty and verminous, deplorable in their habits, ill clad and ill shod, defiant and destructive. Allowance must be made for some exaggeration. Even had the children been little angels, they would not have been welcome guests to some of those on whom they were compulsorily billeted. But the complaints were by no means without substance, nor did they relate only to a very small proportion of the children. A group of professional women, acting upon a resolution from the National Federation of Women's Institutes, set themselves to find out the truth about these accusations, and *Our Towns: A Close Up*[1] is the horrifying result. The report is addressed to readers who have stout stomachs and an appetite for facts, however disagreeable the facts may be. It takes refuge in no polite euphemisms. It does not refer to scabies as "shelter rash" or to lousiness as "uncleanliness." Evacuation proved to be a window through which town life in its more squalid aspects was revealed. What it showed was poverty, but a poverty which was not so much lack of means as lack of personal discipline and social standard. One town clerk in a reception area states that as the children defiled on arrival "the heads of some of them could be seen crawling with vermin." In another area some of the children arrived in garments so verminous that these had to be immediately burned. In another, 23% of the evacuated children were found to have head lice, and, what is worse, the cleansers found many of them reinfested after every visit from relatives and friends. Dr. Kenneth Mellanby had previously given some idea of the extent of the infestation with head lice.[2] He had shown that in a sample of children from ten industrial cities over 50% of the girls between the ages of seven and eleven were infested. In the country infestation is regarded as a disgrace: in the towns it is treated as a lighter matter.

Other evidence which startled the people concerned out of their customary modesty related to insanitary habits among the children, testifying to a low standard of behaviour in the places from which they had come. Enuresis was found to be common at all ages up to fifteen years. Among the younger children this might be an infantile reversion due to a new sense of insecurity, but there were a substantial number of other cases of a more difficult type, without any detectable medical origin. A school medical officer in Surrey says that the problem of enuresis was much eased by the return to London of the worst cases of the slothful or untrained type; another in Essex attributes the condition to lack of early training. Faecal incontinence was also a great difficulty. "Some of the younger [children]," say the compilers of this volume, "were said to be wholly unaccustomed to use a closet and to have used the hearth or corners of the room for defaecation." This is a reflection not only upon the training of the children but upon the housing conditions. It is stated in *When We Build Again*, a publication of the Bournville Village Trust, that in 1935 Birmingham had 38,773 back-to-back houses, 51,794 houses without a separate water-closet, and 13,650 without a separate water supply. In Shoreditch there are said to be numerous three-story houses occupied as tenements by three families, sharing two closets, one at the top of the house and the other perhaps forty feet away in the yard outside.

All this and much more comes within the uncomfortable beams of this searchlight. The remedy lies partly in the provision of better and more sanitary housing, but that will not meet the case of children whose parents are neglectful and lazy and incompetent. The defects in behaviour reflect not only upon the parents but to some extent upon the teachers and upon the educational system, which instructs the children in remote geography but forgets entirely their own bedrooms and backyards. Schools could teach biology in such a way as to relate it to personal hygiene and behaviour. They could teach many other intimate and personal things which more fortunate children learn in their own homes. But, unhappily, the schools and their medical services do not get hold of the children until it is too late. It is not the Jesuit alone but the sanitary educationist who wants the child up to the age of seven, or even only up to the age of five. As things are, the five-year-old enters school suffering from complaints and faulty habits which the school doctors and nurses will spend the next nine years of his life in trying to eradicate. The best efforts of the school medical service are frustrated also by the reservoir of infestation and contagion in the pre-school child. The compilers of this report have been impressed by nothing so much as the need to multiply nursery schools in the poor quarters of towns. In such schools good eating and sleeping habits and cleanliness in body and behaviour could be inculcated, and the child learn discipline and self-respect. The wide extension of nursery schools will be costly, but less costly than dirt and disease and delinquency. It is the nursery school, if anything, which can break the insanitary entail and prevent the sins of the fathers—more often the sheer fecklessness of the mothers—from being visited upon the children. Prof. R. J. A. Berry, in a letter to the *Times* last month, pointed out that many of the unpleasant features revealed by the evacuation of children are precisely those characteristic of feeble-mindedness, and said: "If the parents themselves are feeble-minded then the sooner the child is removed, even if only for part of the time, to a nursery school, the better for the child and for those who sooner or later have to pay for its segregation. At the moment the educational system catches the defective a little too late."

ACID PHOSPHATASE AND PROSTATIC CANCER

The results obtained by Huggins and his colleagues[1] in the treatment of prostatic carcinoma have aroused much interest in the physiology of this gland, and more particularly in its ability to secrete a special type of phosphatase. The group of ferments to which it belongs, the phosphatases, have the power of liberating inorganic phosphate from hexose phosphate and other organic phosphorus compounds. They exist in many tissues, and their production is a manifestation of cellular activity. Many types

have been described, but two are of outstanding clinical interest: the alkaline, which comes chiefly from bone cells, and the acid, which is formed in the prostatic glandular epithelium.[2] Curiously enough, only in man and monkey does the production of acid phosphatase occur in significant amounts, and then only after the onset of puberty.[3] Administration of male hormone to immature male rhesus monkeys leads to a very great increase in the concentration of acid phosphatase in prostate tissue. The suggestion has been put forward that the function of prostatic phosphatase is to split up hexose phosphate and other phosphoric esters in the course of glycogenolysis, upon which human spermatozoa largely depend for the energy requirements of prolonged motility after ejaculation. Although it is unlikely that the enzyme has any function in the glandular epithelium of the prostate, it is probably an important factor in the formation of prostatic calculi. Normally the ferment is excreted in the prostatic fluid, with the result that very little is found in the blood stream. The small amount of acid phosphatase that can be detected in the plasma of a healthy subject is derived from liver, spleen, bone, and kidney.

The information was of academic interest until the discovery of Gutman and his co-workers[4] that tumour cells derived from prostatic epithelium secrete large amounts of acid phosphatase brought the matter into the clinical field. With invasion of blood and lymph vessels by tumour cells a channel is opened to the ferment, so that it can appear in high concentration in the plasma. The Gutmans immediately applied this observation to the differential diagnosis of metastases derived from prostatic carcinoma.[5] They showed that by the method in use not more than 3 units of acid phosphatase per 100 c.cm. appear in the serum of a normal subject. Occasionally a slight increase is detected in the plasma of patients with tumours and other diseases of bone, liver, and other organs not associated with the prostate. Sullivan, Gutman, and Gutman[3] found in a series of 130 patients with bone metastases arising from cancer of the prostate that 110 had acid phosphatase values exceeding 3 units and 95 over 5 units per 100 c.cm. of serum. It would appear, therefore, that a value below 3 excludes bone involvement from prostatic cancer, and that one over 5 almost certainly indicates this. In 3 cases of Paget's disease the acid phosphatase value exceeded 5, but this did not lead to any trouble in diagnosis, because in this condition the alkaline phosphatase is raised, which is not the case with prostatic metastases. In only two instances did any confusion arise: one was in a case of carcinoma of the urinary bladder invading the prostate, and the other in a case of bronchogenic carcinoma with metastases in bone. It should be stressed that an indubitably high acid phosphatase is not usually found unless the skeletal system is involved. The data at present available do not permit one to state precisely how far extracapsular involvement of prostatic carcinoma must extend before a significant increase in plasma acid phosphatase can be detected. Huggins and Hodges,[6] however, showed that injection of testosterone is rapidly followed by an increase of acid phosphatase if there are any metastases in the bones. Accordingly this "provocative" injection of androgen may serve as an excellent diagnostic test of bone involvement when *x*-ray evidence is absent. The same workers went a stage further, and showed that removal of the male hormone by castration[1] or injection of oestrogen[7] led to remarkable clinical improvement, associated with a fall in the acid phosphatase value, which began within 24 hours.

Therapeutic deductions are obvious, but what is of interest here is the opportunity afforded for an objective test to indicate the response to operation. In an excellent review of the whole subject Sullivan and his colleagues[3] have summarized the clinical applications of acid phosphatase estimation. It provides independent evidence of the presence of metastases from carcinoma of the prostate, and it may be helpful in detecting the site of the primary tumour when the prostate is not unduly enlarged. It is of value also in determining when enucleation of the prostate is likely to be of no avail, because any increase in acid phosphatase means that the tumour cells have already reached the skeleton. After removal of a prostate which is afterwards found on histological examination to present signs of malignancy, repeated estimations of plasma acid phosphatase will detect any spread to the skeleton. Finally, if castration or other form of androgen control is carried out, the level of acid phosphatase in the blood serves as a useful means for early assessment of the treatment. The story is not yet finished, because there are hopes of further advances, direct and indirect. Even at this stage, however, there is a strong temptation for the academic investigator to point the moral that even from the most abstruse test-tube investigations matters of great clinical import and therapeutic interest may emerge.

THE PROTEIN RESERVOIR

It has now become so usual to estimate the serum proteins in the study of nutrition, shock, and metabolic disease that Peters[1] has done well to emphasize the implications of physiological work on this subject. Modern studies began when Starling showed that the exchange of fluid between the blood stream and the tissues depended on the balance between the capillary blood pressure and the colloid osmotic pressure of the proteins. The probability of a dual causation should always be remembered in the treatment of oedema. In heart failure oedema may prove intractable if, as the result of malnutrition, serum proteins are even slightly reduced. The ascites and oedema of cirrhosis are as much dependent on a fall in serum albumin as a rise in portal pressure. Because of its smaller molecular size and other properties, the serum albumin is the all-important factor in the maintenance of the colloidal osmotic pressure. Moreover, the globulin is but little reduced by albuminuria or malnutrition, and it may, indeed, be greatly increased in cirrhosis and other diseases in which albumin is diminished. Albumin and globulin are in fact independent variables in the serum, and no determination of the proteins that does not include separate measurement of these fractions is satisfactory. When the clinician finds the serum proteins reduced he is tempted to think they may be rapidly increased by the transfusion of plasma. This is a false analogy with the transfusion of red cells, which exist in a closed system within the blood vessels. Proteins, as Beattie and Collard have shown, flow freely in and out of the vascular system,[2] and the serum proteins are in equilibrium with the tissue proteins. The level of the proteins in the serum can be likened to the level of the fluid in a manometer which communicates with a much larger system. When a dog was starved of protein for 80 days the serum albumin was reduced by 70%, the haemoglobin by 50%, and the body weight by about 20%. But if the percentages are converted into total values, it is seen that of the total protein lost about 80% came from the tissues, only about 3% from the serum proteins, and the remainder from haemoglobin. A moderate deficiency of serum albumin, then, may denote a severe depletion of tissue protein, and for every gramme by which we wish to raise the level of serum albumin 30 grammes must be put into the tissues. If this were more generally appreciated there would be less surprise that in malnutrition serum albumin cannot be restored with great celerity or that the transfusion of plasma is relatively ineffective in the treatment of oedema. A similar line of argument will fortify us against disappointment with the results of parenteral administration of protein autolysates, such as is being developed in the United States.[3] To give only the minimum daily requirement of nitrogen in the form of intravenous injections of amino-acids requires an unpleasantly large volume of fluid. Many lives have been saved by the transfusion of plasma in shock and acute perturbations of the blood volume, but these are conditions in which the body reservoir of protein is intact. Once this reservoir is emptied it is not practicable to refill it by pouring liquid into the manometer—i.e., by parenteral administration of proteins or amino-acids. Reliance must be placed on the natural channel of supply—the assimilation of proteins via the alimentary tract.

PEPTIC ULCER OF THE OESOPHAGUS

Chronic peptic ulcer of the oesophagus has for long been recognized, though it has generally been regarded as almost a medical curiosity. In recent years, however, Jackson and others have suggested that the condition is much less rare than was previously thought, and in a paper recently published R. C. Dick and Sir Arthur Hurst[4] agree with this view. They describe a further series of cases and bring out a number of important points on aetiology, symptomatology, and treatment. Chronic oesophageal peptic ulcers differ in no way in their morbid anatomy from ulcers of the stomach or duodenum; they may vary in size but are usually single. The majority appear to heal completely, causing scarring with or without cicatricial stenosis; malignant degeneration rarely or never occurs. On oesophagoscopy they appear as flat ulcers, with yellowish exudate and hyperaemic zone around, and without the raised fungating edges of a carcinoma. Jackson was able to demonstrate scars of healed ulcers in 67 cases by oesophagoscopy, as well as 21 active ulcers. As with peptic ulcers elsewhere, the acid gastric juice appears to be an essential factor in causation. Dick and Hurst note that in the majority of cases this regurgitates through the cardiac orifice of the stomach owing to incompetence of this opening associated with a congenitally short oesophagus. They quote the findings of Johnstone, in all of whose seven cases there was definite shortening of the oesophagus, but they themselves consider that this shortening is congenital and not cicatricial, being in most cases found with a diaphragmatic hernia of a portion of the stomach. In a very few cases an ectopic patch of gastric mucous membrane occurs in the oesophagus and secretes acid and pepsin just as in the stomach itself.

The symptoms of chronic ulcer of the oesophagus differ from those of carcinoma or of "cardiospasm" in a number of ways. Pain is often severe and appears during eating or drinking—at first only with hard or irritating food, but later with almost every meal. It may also be felt later after eating if the patient bends forward or lies down; it may be relieved by sitting up, or by stretching the arms above the head, though this only happens in cases associated with a diaphragmatic hernia. The pain is situated deeply in the middle line behind the lower end of the sternum, and may come and go just as in ulcer of the stomach, with periods of freedom lasting even for years. The natural tendency is towards recovery, but in about half the cases there is gradual dysphagia due to spasm; occasionally organic stricture develops. With stricture, retention of gas in the stomach may take place as well as obstruction to the passage of food from above, and the rare condition described as "aérogastrie bloquée" may then result, with intense gastric dilatation. The diagnosis may be confirmed by *x*-ray examination or oesophagoscopy may be employed, though, owing to associated spasm, the ulcer cannot always be seen. If there is clinical suspicion of oesophageal ulcer—as suggested by the symptoms, findings of occult blood in the stools, and perhaps haematemesis—special methods of *x*-ray examination should be adopted. The simple fluid barium emulsion does not often reveal the ulcer, and a semi-solid meal is required: the patient should swallow it lying down, the foot of the bed being raised. The characteristic picture of spastic narrowing with a central ulcer niche can often be recognized, as well as a portion of the stomach lying within the thorax above the diaphragmatic opening.

In treatment, fluid feeds are necessary at first, but need not be given as frequently as in gastric or duodenal ulcer; the patient is better sitting up; the bed should be raised at night so that the head is high, in the hope that regurgitation of gastric contents into the oesophagus will thus be prevented. Atropine and olive oil are also recommended. If such medical measures fail, gastrostomy is advisable, and was required in 2 of the 16 cases described by Dick and Hurst. Some after-care on similar lines to the active treatment is important to prevent recurrence.

With careful diagnosis and thorough treatment the prognosis is good, and although oesophageal ulcer is not common, it is important that it should not be forgotten when obscure cases of early gastric pain or dysphagia are encountered.

REFRIGERATION ANAESTHESIA

Baron Larrey, Napoleon's army surgeon, is said to have amputated limbs painlessly at the Battle of Eylau in a temperature of –19° C. The deliberate use of cold, however, to obtain anaesthesia, while well known, and subjected to spasmodic attempts at popularization,[1] has never been taken up seriously, largely through the fear of damaging the tissues and the practical difficulties of refrigerating more than small areas of the body surface. The experience of Crossman, Allen, Hurley, Ruggiero, and Warden[2, 3] suggests that it is a useful method of anaesthesia for amputation in "poor-risk" patients in whom the circulation in the limb is already failing. For efficient refrigeration of a limb—and their report deals with the lower limbs only—a tourniquet is essential. They emphasize that the main harmful effect of a tourniquet is by direct pressure, particularly on nerves, and to minimize this they advise narrow gum-rubber tubing. Experiments on animals have shown[4] that a limb will survive up to 12 to 15 hours' deprival of blood supply at ordinary temperatures, and very much longer when cooled to just above freezing-point. Ligation of a limb causes shock, which after 6 to 8 hours may be sufficient ultimately to kill the patient. Human resistance to this form of shock is high, and little ill effect of the sort need be expected from a ligation lasting 2 to 3 hours. Cold lowers the resistance of the tissues to infection, but the activity of bacteria present is decreased. Objection to cold might be made on the ground that the trickle of blood in the arteriosclerotic limb threatened with gangrene would be still further reduced and real danger arise of sloughing flaps. This is more than offset by the lowering in metabolic activity of the tissues, with consequent reduction in oxygen need and carbon dioxide production. One great advantage of the use of refrigeration is that no preparation other than a mild sedative in the occasional apprehensive patient is required. The authors use either ice or electrical refrigeration to cool the limb, and have found that the time of cooling to produce anaesthesia varies from 1 hour for a foot to 2½ hours for a thigh amputation. Frostbite does not occur, and the skin temperature does not usually fall below 40° F. As Rupp[5] points out, refrigeration may prove useful in other directions. It would probably lengthen the time during which embolectomy could be undertaken, and it might be invaluable for cases inoperable by any other method.

VENEREAL DISEASE IN SWEDEN

The large rise in the incidence of venereal diseases in Britain since the beginning of the war has attracted widespread comment. In discussions on the thorny problem of prevention and control comparison has been made with the experience of Scandinavian countries, where legislation has been in operation for some years. A law to combat venereal disease was introduced in 1918 in Sweden, and this lends special interest to an examination by Dahlberg[6] of the trend of the incidence of venereal diseases in that country from 1913 to 1938. Legislation and the methods adopted for the control of venereal disease were, it appears, very successful in the case of syphilis, but made little impression on the trend of gonorrhoea. After a slow rise in the incidence of venereal diseases during the first years of the last war a rapid increase occurred in 1918 and 1919. By 1919 the number of cases of soft sore and of syphilis at ages over 1 year had been almost trebled, and the incidence of gonorrhoea was double that of 1913-14. At ages under 1 year the number of cases of syphilis rose suddenly in 1919 (followed by another small rise in 1920) to three times the previous figure. Between 1919 and 1923 the incidence of syphilis fell rapidly from 6,354 cases in the former year to 1,127 in the latter—i.e., to about half of the pre-war level. The fall continued more slowly, and in 1925 only 723 cases were recorded. This trend was interrupted by a rise to over 1,100 cases in the boom years of 1927-31. After this the prevalence of the disease again fell rapidly, and the average number of cases annually in 1936-8 was only 352, compared with 2,478 in 1913-15. Soft sore followed a similar course but with a relatively greater decrease: the annual cases numbered only 81 during 1936-8, compared with 1,387 during 1913-15. Congenital syphilis declined at a much slower rate, and it was not until 1928 that the trend returned to the pre-1914-18 level. In the last three years an average of 9 cases was recorded, as against 30 during the first three years of the period (1913-38). The curve for gonorrhoea differed from that of syphilis in the later years, though to begin with it was similar. Between 1919 and 1923 notifications of gonorrhoea diminished from 20,594 to 10,321—to pre-war level. They then rose until 1930, when 14,388 cases were recorded, and afterwards decreased but remained above the pre-war level. The annual average number of notifications of gonorrhoea in 1936-8 was 12,125, compared with 10,621 in 1913-15. The percentage of male to female patients was approximately 70 for syphilis and 90 for soft sore, and only small fluctuations occurred in this percentage during the twenty-six years. The male percentage for gonorrhoea, however, has shown a progressive fall from 80 in the beginning of the period to 70 at the end.

Dahlberg considers that the difference between the trends of gonorrhoea and of both syphilis and soft sore may be due partly to the difference in the diseases. Gonorrhoea, being more contagious, is consequently far commoner than the other two diseases. The symptoms are milder and the patient may optimistically but erroneously believe he is no longer a source of danger to others. There is also a possibility that gonorrhoea may be transmitted during the initial period before the patient is sufficiently aware of it to seek treatment. After discussing various alternative explanations, Dahlberg concludes that the law of 1918 has played an important part in the large reduction of syphilis and soft sore. Diseased males behave with less irresponsibility to prostitutes for fear of penalties, and the instructions which every infected person receives may also have been a factor in the decline of these two diseases.

DIET IN PULMONARY TUBERCULOSIS

The part played by malnutrition in the aetiology of tuberculosis is now generally recognized; yet it is remarkable how scanty is the scientific evidence for this widespread belief. Malnutrition is invariably associated with poverty, and poverty is associated with other factors besides malnutrition. Among these, just how important is the lack of proper food in determining lowered resistance to tuberculous infection? Perhaps the statistical investigation carried out by Knud Faber[1] into the incidence of tuberculosis in Denmark during the war of 1914-18 provides the most trustworthy evidence of the effect of food deficiency on the incidence of tuberculosis. According to Faber it was shortage of first-class protein that caused the rise in tuberculosis in Denmark during the early part of that war, the shortage being due to increased exports. When, later in the war, the blockade prevented these exports, the death rate from tuberculosis in Denmark fell rapidly, though in other countries the rise continued. Dr. George Day, of the Mundesley Sanatorium, has published some interesting observations[2] in relation to the present war and the rationing compelled by it. Over varying periods of time during the past five years several groups of patients suffering from pulmonary tuberculosis have been given different diets. These were: (*a*) restricted pre-war diet, (*b*) unrestricted pre-war diet with extra sugar and injections of insulin, (*c*) wartime-rationing diet, (*d*) wartime-rationing diet with extra sugar. (The extra sugar necessary for the experiment was obtained through the Medical Research Council.) The progress rate of the average patient in each of these groups was calculated from the rate at which his body weight increased, and the rate at which his sedimentin index decreased, as worked out by Day.[3] [4] He found that the patients on (*c*) made much poorer progress than any of the other groups. It appeared, too, that the rate of progress was proportional to the calorie value of the diet. There was not enough evidence to decide whether carbohydrate was the most effective ingredient as a calorie provider. It has always been believed that a diet low in fat predisposes to development of tuberculous disease. Faber blamed protein deficiency. By implication Day suspects the third proximate constituent, and more directly what is common to all three—energy value.

The Honorary Fellowship of the Royal College of Surgeons of England has been awarded to Mme. Chiang Kai-shek in recognition of her great services in the relief of suffering and the advancement of medicine in China.

FORMATION OF INDIAN ARMY MEDICAL CORPS

PROPOSALS OF THE SOUTTAR MISSION

The India Office has announced that sanction has been given to the formation immediately of an Indian Army Medical Corps, to be organized on lines similar to those of the R.A.M.C. The new corps is to include both graduates and licentiates as medical officers. All regular and emergency commissioned officers of the Indian Medical Service will be seconded to it, and it will receive by transfer the whole existing personnel of the Indian Medical Department and the Indian Hospital Corps.

This action follows upon the recent visit to India of the Medical Personnel (Army in India) Mission headed by Mr. H. S. Souttar, Chairman of Council of the British Medical Association. The Mission was sent out by the Secretary of State at the request of the Government of India. In addition to Mr. Souttar, the members were Lieut.-General A. Hood, D.G.A.M.S., Major-General Sir Ernest Bradfield, late D.G.I.M.S., and now President of the Medical Board and Medical Adviser to the Secretary of State for India, and Lieut.-Colonel J. T. Robinson, R.A.M.C., who as A.D.G.A.M.S. has been in charge of medical personnel at the War Office.

The Mission set out in November, and on the way to India spent eight days in Egypt, devoting the time to an intensive investigation of the Indian hospitals, both general and C.C.S., in the Near East. They arrived in India in the middle of December, spending a month there, first visiting Delhi for an interview with the Viceroy and the heads of Departments. Other places visited were Calcutta, Lucknow, Lahore, Bombay, Poona, and Karachi. At Calcutta they met the leaders of the different medical associations.

Indian Medical Resources

The two sources of supply of doctors in India are the graduates (about 12,000) and the licentiates (about 35,000). The graduates are men who have passed through a full medical curriculum and have acquired a qualification which is registrable in the United Kingdom. Many of them have attained distinction and are capable of specialized work of a high order. For the licentiates there is no exact parallel in the medical profession in this country. They vary considerably in primary education and professional attainments. But their training, which twenty years ago was very poor indeed, has been improved, and many of them are skilled doctors who compete successfully in civil life with the university graduates. In two Provinces the status of their medical school has recently been raised and accepted as that of a college giving training for a university degree recognizable by the General Medical Council. All licentiates have passed examinations at the end of a four-years curriculum, and many have had several years' experience in practice.

The Mission, on their visit to Cairo, made special inquiries about the work of the licentiates in the field, and their own observation and the opinion of the commanding officers were that these men were capable of full medical responsibility, which up to now, together with the status and emoluments of members of the medical profession, they have been denied. They were judged by the Mission to be a loyal and hardworking body of men, not inferior in intelligence and capacity to a large number of graduates. Their main grievance, which is one of substance, is the withholding of professional responsibility and status.

The licentiates come from a financially poorer class of the community. The education of many of them has been subsidized by the Government, and in return they have had, after qualification, to engage for four or five years in Government service. In the Army, while the graduates receive full commission and pay, the licentiates can only receive the Viceroy's commissions, their pay is Rs. 75 a month (supplemented, it is true, by fairly good allowances), their pension rates and the pensions for their dependants are on a low scale, and on service they are not treated as members of the officers' mess.

The Mission proposed—and it has been accepted by the Government—that all candidates for a commission in the new corps, whether graduates or licentiates, should be required to undergo at least a three-months probationary course of training in India in those subjects which are of importance for military service. During this course they will receive instruction in such subjects as anaesthesia, blood transfusion, war wounds, nutrition, tropical diseases, and hygiene. They will be under close observation during this period, a certain amount of selection and classification will be possible, and the bestowal of a commission will turn upon the report given by the commandant. The outstanding feature of the new arrangement is that to every doctor who has qualified to practise in India will be given the opportunity to rise to any position in the corps which his abilities justify. Licentiates will receive commissions with the status to which they are entitled.

Creation of an Army Nursing Service

The other great advantage of the new corps is that it will make possible a service of orderlies of the type and training which Army nursing requires. The virtual absence of an effective nursing service from the Indian Army greatly impressed the Mission. There are only 300 registered male trained nurses in the whole of India. The bulk of the nursing is carried out by sepoys, who receive only a brief military training before they are turned into the wards to do nursing. Although the reorganization of the medical services of the Indian Army has been the subject of many reports during the last twenty years, apparently the importance of male nursing personnel as a vital part of Army medical service has escaped attention in these inquiries. An immediate attempt is to be made to attract to this service men of a superior class, who will be given an effective training in elementary nursing and first aid, with adequate pay and prospects of promotion, and it is believed that recruits will not be lacking and that in due course the Army in India will have a system of nursing orderlies like the first-class men on whom the R.A.M.C. depends.

The Mission were impressed by the possibilities of the training centres which they visited, and they took the view that if people of the proper class were recruited and technical training carried out by warrant-officers and N.C.O.s from existing sources and from compounders and male nurses, the same effort and expense would yield immensely superior results in the shape of "other ranks" personnel to those which have been hitherto forthcoming.

The effect of these changes upon the Indian Medical Service has been very gravely weighed and considered. That Service, which in one form or another dates back now for more than 180 years, has done magnificent work. Although it is now primarily a military service, responsible for the medical care of the personnel of the Indian Army, Navy, and Air Force, it was originally a civilian service which provided doctors for the Army. It has also been responsible for medical education, public health administration, and research. Its officers founded the first medical colleges, and until recently provided the majority of their teachers. It was the pioneer in the teaching and practice of Western medicine in India.

At the outbreak of the war the members of the Service numbered 780, of whom 59.6% were Europeans. The number is now 2,838, of whom only 19.9% are Europeans, so that the wartime increase has been almost entirely in the non-European element. The figures suggest the great change which has come over the Service. Meanwhile, there are these 35,000 licentiates, holding qualifications registrable in India but not in the United Kingdom, who, because they do not hold the recognized degrees, are not, under the existing law, allowed to receive commissions in the I.M.S. The Service has great responsibilities outside the Army. It would be impossible to embody it in the new corps, but to that corps its officers will be seconded. As for the other two organizations, whose personnel is to be transferred, the members of the Indian Medical Department will have a greatly improved position. The Department has two branches, British and Indian. Recruitment to the first is restricted to domiciled Europeans and Anglo-Indians, who take a five-year course at a medical college and obtain a diploma which entitles them to practise in India. Those who acquire a qualification registrable in the United Kingdom have been granted commissions in the I.M.S. The members of the Indian branch, who have received the licentiate's diploma, are entitled to practise in India only, and assist I.M.S. officers in the care of Indian troops. The other organization, the Indian Hospital Corps, is composed of persons intended for the performance of the same duties in hospitals, laboratories, medical stores, and field medical units as "other rank" personnel in the R.A.M.C., but it has never provided an adequate or satisfactory service.

This decision to form an Indian Army Medical Corps, a homogeneous Service of officers and other ranks, in all respects similar to the R.A.M.C., may well have a profound effect for good on the Indian war effort. The speed and thoroughness with which the matter has been carried through—almost without precedent for expedition in the slow-moving East—are a matter for congratulation alike to Mr. Souttar and his colleagues who undertook this strenuous and urgent duty and to the authorities in Delhi and London who facilitated their recommendations.

MODEL INDUSTRIAL MEDICAL CENTRE

An excellently equipped medical centre has lately been opened at the works of Morris Motors Ltd. of Cowley, Oxford. It is one of two blocks covering a floor space of 7,000 sq. ft. which are devoted to welfare, the second block housing various clubs and athletic activities. The medical centre is in the charge of a full-time works medical officer, assisted by State-registered nurses, and it has been built and provisioned on what may be described as the Nuffield scale. It is a quiet, attractive building, with a surgery for dealing with minor injuries—serious cases of injury are sent to hospital—an *x*-ray department, a physiotherapy unit, dental and ophthalmic departments, rooms for the staff, an almoner's office, and a waiting-room (but the arrangements are such that waiting is reduced to the minimum). The aim of the centre is diagnosis and prevention. It is provided with an electrocardiograph, a four-valve *x*-ray apparatus with rotating anode tube and an attachment for tomography, apparatus for blood-testing, and other diagnostic aids. The treatment of injuries is also undertaken, and ultra-violet lamps and short-wave and other apparatus for physiotherapy are provided. The dental department has its own *x*-ray equipment and up-to-date anaesthetic outfits; the well-equipped ophthalmic department is staffed from the neighbouring eye hospital.

In the arrangements for dealing with workers at this centre, all accidents, however trivial, are reported to the surgery; all newcomers to the factories may undergo a medical examination with a view to direction to jobs suited to their physical capacity, and a card index is kept of the medical history of every employee. It is hoped that from this centre a useful contribution will be made not only to the industrial health of the workers at Cowley but, by mass observation of sickness under factory conditions, to the new science of social medicine, for which there is now a chair at Oxford. It is intended to equip the *x*-ray department for the mass radiography of chests, and all employees with signs of tuberculosis will be sent for sanatorium treatment. A close liaison is maintained with both insurance practitioners on whose lists these workers are and the staffs of the hospitals, and when it is discovered what is wrong with a patient he is referred for treatment either to his practitioner or to the hospital as the case may be. In the dental department the dental surgeon examines and advises workers free of charge, carries out any extractions or conservation work, and makes dentures in the new plastics, at normal insurance rates. In the eye department employees who wish to have their eyes tested first obtain the necessary vouchers, if they are members of the contributory scheme, entitling them to examination and prescription, and then they are expected to make arrangements with their own opticians for the supply of glasses. The whole of the medical department is a part of the welfare work of the Nuffield organization, and the medical officer maintains close touch with the welfare supervisor, the social secretary, and others on that side.

Research into Nutriment of Canteen Meals

Another interesting welfare department at Cowley, opened on the same occasion, is a food research department, a joint enterprise of the Nuffield organization and Barkers (Contractors) Ltd., who are responsible for operating the canteens at the works. A biochemist is in charge, a dietitian and a chef are on the premises, and the laboratory is equipped with centrifuges and other apparatus for investigating the composition of foods. Study is also made of the problems of cooking and service, which are important factors in communal feeding in view of the unstable nature of food after its preparation for the table. To ensure that canteen meals are palatable, satisfying, and in conformity with dietetic principles will be the task of this department, which will report daily on the number of calories served per portion. The laboratory, which will impose its own improved standards on the canteen managers, is believed to be the only one directly connected with an industrial canteen. One of its first activities is, by means of a mobile laboratory, to go the round of the canteens and make researches on the spot on the stability of vitamin C in food prepared by what may be called mass cooking. The Ministry of Food has co-operated in this venture, and it is hoped that a certain amount of academic research on nutrition may be undertaken.

TRANSFUSION ACCIDENTS AND DEATHS

The memorandum printed below has been drawn up by the Blood Transfusion Research Committee of the Medical Research Council for circulation by the Ministry of Health to hospitals of the Emergency Medical Service and to the Maternity Services throughout the country.

If following a transfusion the state of any patient gives rise to anxiety and it is felt that the condition can reasonably be ascribed to some effect of the transfusion, it is requested that the incident should be immediately reported by telephone to the nearest blood supply depot in the London area or regional transfusion laboratory in the Provinces, so that any necessary investigations can be initiated at the earliest possible moment. At the same time the hospital pathologist should be informed.

The conditions which it is particularly desired to investigate are haemolytic reactions, and reactions due to deterioration or contamination of the blood or blood derivatives used for transfusion. Although these reactions produce very variable clinical pictures it is suggested that the occurrence of any of the following symptoms or signs following transfusion should be notified: sudden grave collapse, acute severe backache, haemoglobinuria, or jaundice. Rigors and febrile reactions should not be notified unless they are accompanied by one or more of the above signs or symptoms.

The investigations in such cases would be made very much easier if a sample of the blood, or blood derivative, from the bottle given was available. It is therefore requested that a few c.cm. should be left in every bottle of transfusion fluid given and that this should be kept in the bottle for at least 24 hours, and not thrown away until the patient has been revisited and it has become clear that he has not reacted unfavourably to the transfusion. As a routine, therefore, every bottle should be recapped after transfusion and put in a cold place (in a refrigerator if possible). The giving apparatus should be removed and washed immediately in cold water as usual.

If for any reason it proves impossible to make immediate contact with transfusion headquarters it is requested that a sample of blood should be withdrawn from the patient under sterile conditions, using a dry syringe if possible, and divided between two dry sterile tubes and one dry oxalate tube (for blood culture and other examinations). At the same time a clean specimen of urine should be obtained from the patient and kept. In the ordinary way these specimens of blood and urine will be collected by the transfusion officer when he arrives to see the case.

CAMPAIGN AGAINST TUBERCULOSIS

Some information about the steps already taken by the Government in its campaign against tuberculosis, particularly the stage reached in the supply of miniature radiography units to local authorities, was given by the Minister of Health at a Press conference in London on April 29.

He said that with the aid of expert advisers a detailed scheme covering the application of the system of miniature mass radiography in all its aspects had been drawn up, and full information was being sent in a comprehensive memorandum (Memo. 266/T) to all local authorities responsible for the treatment of tuberculosis. At the same time these authorities were being given full particulars of the new scheme of allowances. Two of the new mass radiography machines had now been delivered. The first was being used to train operational teams. The second had been delivered to the Lancashire County Council. As more of these units were produced they would be allocated in the following order: L.C.C., Middlesex C.C., Surrey C.C., Wales (Welsh National Memorial Association), Staffordshire C.C., Leeds, Newcastle-upon-Tyne, Nottingham, Essex C.C., Portsmouth, Bristol, Manchester, Sheffield, Birmingham, Liverpool, Norwich, and Northamptonshire C.C.

At present about one machine a month would be delivered. It might, therefore, take at least a year before there was a network of mass miniature radiography units operating in the most populous areas of the country. It was hoped that eventually miniature radiography would be a part of routine health examinations. To begin with, arrangements would be made, as the units gradually become available in different parts of the country, to examine suitable groups of people—ordinary healthy men and women—in places such as industrial establishments, offices, factories, or any place where large numbers of people could readily be assembled.

Only about three out of every 1,000 persons examined were found to be tuberculous and needing treatment. The miniature x-ray machines could photograph chests at the rate of more than 100 an hour, using ordinary cinema film. Each negative, only about one inch square, was later projected on a screen and examined by experts. Doctors could sort out the cases—perhaps 40 or 50 in every 1,000—where there was some suspicious sign which should be investigated further. In the small number of cases in which tuberculosis was diagnosed sanatorium or dispensary treatment would be recommended.

The Government had decided to provide special maintenance allowances, which would enable those persons found to be affected to give up work for a while and undergo treatment. These allowances would apply to everybody undergoing approved treatment, no matter through what means the diagnosis had been made. They would be administered by tuberculosis authorities as part of local health services, and would comprise "maintenance allowances" based on a standard scale and without any test as to means, to which might be added, at the discretion of the authority, extra grants or special payments towards commitments.

Allowances

The weekly allowances, to which Mr. Brown referred, are as follows: for a male applicant and wife (or female applicant with dependant husband) 39s.; for male or female applicant where the former rate does not apply 27s.; for dependants (other than wife or husband) aged 16 and over 12s.; 14 to 16 8s.; 10 to 14 6s. 6d.; under 10 5s.

Where the applicant is a person living as a non-dependent member of a parent's or other relative's household and is receiving treatment at home the allowance will be 25s., with additional payments if the person has dependants as stated above. To these will be added any special payments made at the discretion of the local authority.

The same rates apply to Scotland, where similar information has been given in a circular to local authorities.

Reports of Societies

ANALGESIA AND ANAESTHESIA IN OBSTETRICAL PRACTICE

At a meeting of the Section of Obstetrics and Gynaecology of the R.S.M. on April 16, Dame Louise McIlroy presiding, the discussion was on "Analgesia and Anaesthesia in Obstetrical Practice."

Dr. John Elam, who defined anaesthesia as relief from pain with loss of consciousness, and analgesia as relief without loss of consciousness, said that one of the essential things to remember before confinement was not to frighten the patient. Pre-medication was important, but should not make the patient too sleepy. When forceps was contemplated he had found potassium bromide and chloral helpful. The objection to barbiturates was that the patient on coming round was restless and perhaps uncontrollable. He acclaimed the virtues of the Oxford vaporizer, in which he used a mixture of trichlorethylene and ether. When it was necessary to use forceps in domiciliary midwifery he had felt quite safe with the Oxford vaporizer, doing the induction himself and then leaving the apparatus to the midwife. If there was overdosing with trichlorethylene labour was slowed down, but the moment administration was stopped the pains began to return, and within ten minutes were as strong as ever.

Prof. A. M. Claye spoke on the question of the effect of maternal anaesthesia and analgesia upon the infant, and summarized recent literature. He dealt in particular with the allegation that analgesics in labour, given in greater amounts than the pharmacological dosage, might be a factor causing anoxaemia with cerebral damage to the child. One extensive investigation, however, extending over 800 cases, suggested that cerebral injuries were due to mechanical factors—that is, faulty obstetrical manipulation—rather than to drugs given to the mother. His own conclusion was that the technique of administering anaesthesia and analgesia in common use in obstetrics required a great deal of learning. Probably the most fool-proof apparatus was Minnitt's. With the concentration of gas used it was virtually impossible to harm mother or baby. The success of more difficult methods depended on the acquisition of the necessary skill.

Dr. Grantly Dick Read said that he spoke as a general practitioner with an experience of thirty years' observation of normal and natural function. It was rather noteworthy that the Fellows of the R.C.O.G. probably attended only 1% of deliveries in this country, and yet it was they who continued to teach how obstetrics should be conducted. How many of them knew the phenomena of normal labour? It was assumed that normal labour was a painful process. He entirely disagreed. There were three types of labour: normal or natural, cultural, and abnormal or surgical. Cultural labour was the product of the institutions of civilization, which had introduced the woman to all manner of fears and tensions as she approached childbirth. If there was imbalance between the structures which received a stimulus and those which interpreted it, then normality and natural function were broken down. Fear and anxiety in this connexion did not persist among less cultured and more primitive races. It was this neurological factor which gave rise to the pain in normal labour. By eliminating fears *ab initio* a painless labour might be induced. Pain was dependent on certain tensions occasioned by inhibition of the function of labour. Painless labour did not occur in all normal cases, but the percentage was rapidly increasing, and as more and more midwives applied themselves to eliminate fear ante-natally and to teach the women the physical aspect of relaxation it would still further increase. By the teaching of relaxation, a certain readjustment of diet, and certain forms of exercise, combined with normal and reasonable ante-natal treatment, anyone who had the courage to try it out on 50 normal cases in succession would have an "eye-opener." He suggested more research into the psychological and the neuromuscular aspects of labour.

Mr. R. H. Paramore said that he found it extremely difficult to differentiate between the normal and the abnormal. There were borderline cases, and it was next to impossible to say what might happen. Childbirth was a laborious affair, involving much hard work during which the viscera were greatly compressed. No woman, in his opinion, should be submitted to a second stage of labour lasting longer than two hours, and in view of the shortness of the second stage in multigravidae one might well ask whether in the case of a first child one should wait so long. With the cervix fully dilated, extrusion of the child could occur only with great distension, and laceration of the tissues was common. He commended the use of spinal anaesthesia. No other method of anaesthesia to his knowledge had the same effect. Bleeding was much less with spinal anaesthesia than with general; and it had other advantages.

Dr. J. Mickiewicz gave the results of continuous pentothal anaesthesia in a series of 29 cases of Caesarean section, performed by Mr. Carnac Rivett at Queen Charlotte's. Anaesthesia was induced with 0.5 g. of pentothal in 10 c.cm. of saline; 2% pentothal was added from time to time to maintain the anaesthesia. It was usually found that the addition of from 2 to 10 c.cm. of the 2% solution at roughly 5-minute intervals was sufficient. The total dosage for Caesarean section was about 1.5 g. Coramine and oxygen were available in case of respiratory depression, but this had rarely been encountered. Atropine (1/100 gr.) was given one hour before operation. In this series there had been one maternal death on the fourth post-operative day, due to acute paralytic ileus, and there was one foetal death (on post-mortem examination the lungs were found to contain liquor amnii; this must have been due to premature respiration, not to respiratory depression). Dr. B. A. Sellick gave particulars of 251 cases at Middlesex Hospital in which intravenous pentothal had been given. They had included 33 cases of surgical induction, 95 of forceps delivery, 5 of post-partum haemorrhage (manual removal), 20 of Caesarean section, and 91 of perineal laceration. Two maternal deaths occurred—one after post-partum haemorrhage and one after Caesarean section—and there were 7 stillbirths. Six of the mothers and 10 of the infants required resuscitation. Miss Young gave some account of the training of midwives in the administration of gas-and-air anaesthesia. Out of 51 midwives of the Middlesex C.C. this last year, 25 were so trained. Captain A. C. Frost, R.C.A.M.C., mentioned the value of paraldehyde given per rectum. Dr. Russell said that the ideal anaesthesia was one in which quick induction was possible, and in which the patient could come out of the anaesthetic quickly.

Dr. Letitia Fairfield referred to a collection of statistics of 950 cases of Caesarean section, drawn from 20 different units in the course of six years. There had been six deaths from anaesthesia, and in all the six it was spinal anaesthesia which had been used. Everything was being done in L.C.C. hospitals to teach relaxation and the practice of normality, and to instruct the midwife in these respects, but, of course, this had been given varying emphasis in different hospitals. She had seen many women who had been carefully trained in relaxation methods, and in some cases the women had had remarkably painless labours, but in others the labour had been very painful. While relaxation was important, she suggested to Dr. Dick Read that he should not "oversell" it. The discussion ended with a final brush between Prof. Claye and Dr. Dick Read, the former suggesting that Dr. Read did the gynaecologists less than justice if he thought that they did not consider the psychology of their patients. Dr. Dick Read replied that he was not offering a panacea for all labours. Neither his own method nor any other was successful in all cases.

Correspondence

Private Practice

Sir,—On the assumption that all the population is insured against sickness and accident (paragraph 431 of his report) Sir William Beveridge makes the following observation: "The possible scope of private practice will be so restricted that it may not appear worth while to preserve it." This is the view of an economist, and it seems to me that, from this point of view, the position of private practice alongside a complete State Medical Service, if this takes a form acceptable to both doctors and patients, has perhaps not been sufficiently studied by our profession.

First, what is meant by private practice? Under the State scheme the patient's first and most intimate contacts will be with general practitioners. Behind them, however, there will be consultants, specialists, dentists, nurses, masseuses, pharmacists, opticians, instrument makers, etc. Will the private patient be allowed to choose for which of these services and the goods they supply he will pay, or will it be a case of paying for them all? If the former privilege is allowed, I suggest that many patients who would prefer to employ a G.P. in a private capacity will be less desirous of paying fees to the numerous shadowy, often unknown and fearsome, figures who, to them, work in the slightly sinister background of hospitals and laboratories. In the latter case, during the course of a long and expensive illness, many private patients will surely decide that their financial limit is reached, and they will seek the refuge of the State service.

It must be remembered that every private patient will be paying twice for any service or remedy he receives, and that the number of these patients will be much smaller than under present conditions. It is not, therefore, unfair to assume that the level of fees of private patients will be higher, and this for two reasons. First, either because they will belong to the wealthier classes, or, secondly, because they will be difficult, contentious folk, who take up more of our time than the average patient over non-essential details. My own experience has been that many patients who are entitled to medical benefit under the present scheme, whatever their parents' or husbands' income may be, do not hesitate to claim their rights: this has been quite noticeable during the present emergency. There is also an increasing tendency for the more prosperous section of the community to subscribe to the extended benefits contributory scheme or some similar organization. A man earning £1,000 a year, with a wife and two children, pays £300 a year in income tax at present rates, and I suggest that up to this income level very few people will be private patients; and even above it many will take advantage of a State service. Examination of income-tax figures for 1941-2 shows that only 2.1% out of fifteen million people assessed for income tax return gross income of more than £1,000 per annum.

It would appear, therefore, that the retention of private practice in a 100% insured population is likely to be a small asset to general practitioners, and much smaller to other members of the profession and to the members of the auxiliary services mentioned above. Furthermore, it will almost certainly be a diminishing asset for this reason. Practically every member of the community starts his or her career on a small salary or wage, and will at this period take advantage of the comprehensive free health service provided by the State. We believe that this will be a good and satisfactory service, so that as their prosperity increases such people are unlikely to change over and become private patients.

I suggest, therefore, that if 100%, or even 90%, of the population is completely insured the retention of private practice should have no place in our financial negotiations with the Ministry of Health. If it is allowed to intrude the Minister is almost certain to use it as a means to whittle down both our freedom and our remuneration, and it may even seriously prejudice any claim to compensation for the capital value of practices.

One other point not connected with the economic aspect. Many of us believe that the medical profession has lost status and prestige with the community. Discussions with the laity have led me to the conclusion that this is to some extent due to the widespread conviction that the contract or institution patient does not get so much care and attention as the one who pays. The justice or injustice of this conviction is impertinent to the argument; it undoubtedly exists. If private practice is permitted I feel it would be to our advantage to eliminate the possibility of this accusation by not allowing any doctor to do both types of practice. In conclusion, I have been in general practice for 23 years, and nine-tenths of my professional income is provided by private patients' fees ranging from five shillings to one guinea.—I am, etc.,

Birmingham F. B. Winfield.

"Capacity to Pay": A False Premise

Sir,—From the tone of certain recent statements and articles it may well be deduced that the future of the medical services in this country has been predetermined by bureaucracy, and that our profession will now be expected to accept its scheme as a *fait accompli*. Whether this is so I have no means of telling, but it is abundantly clear that the underlying motive for any change is a political one, which bears no relationship to any real need of the populace or to the outcome of any unbiased inquiry into the quality of the medical services that exist to-day. We all know that the easiest diseases to cure are those which the patient has not got, and yet we are acquiescing in this spurious diagnosis and allowing bureaucracy to foist upon us its quack remedy so that it can gain a false credit for cure.

It cannot be denied that there is a suggestion of fanaticism in the urgency with which the "reformers" pursue their object —a fanaticism which would be worthy of an altruistic ideal— but let us not be misled, for the motives underlying most political moves are far removed from altruism. The politician, whether in Parliament or outside, cannot rid himself of the human frailties which hanker after personal publicity, cheap popularity, acquisition of power. And so, instead of a scientific assessment of the pros and cons of the case, we find the whole issue prejudged and bolstered with false statements which are made to appear axiomatic.

As an example of this I quote the opening paragraph of a discussion, or rather a dictate, on a national health service which appeared in a responsible journal having a fairly wide circulation among a presumedly intelligent section of the public. It ran: "Twenty-five years hence Britons will shudder as they recall the incredible situation which existed, say, in 1943, when medical treatment depended on the capacity of the individual to pay for it." We, as doctors, are in a position to know how false such a statement is, but the great majority of the readers, being lay people, are likely to regard it as the truth. On the day that statement appeared I walked through the wards of a hospital and saw patients being treated with hundreds of pounds' worth of radium, some having *x*-ray therapy from most expensive plants, others having costly series of injections, many recovering from extensive operations followed by skilled nursing and after-care, and so on. The point is that these patients will either pay nothing at all or at most a small contribution to the actual cost of their board and lodging in the hospital, and this is multiplied ten thousand times throughout the country. In the face of all this we are asked to believe that "medical treatment depends upon the patient's capacity to pay for it." The most generous interpretation would be to assume that the journal really thought that it was living up to the quotation with which it emblazons its title: "The assertion of the truth." But a Press which is so ill informed has no moral right to express opinions for the guidance of others.

Since the war started the wildest statements have been made concerning medical organization which, while good propaganda for a State Medical Service, have no relation to the facts. I have conscientiously looked back over a surgical career of thirty years and can honestly say that in that time I have not known any patient lack adequate surgical treatment on account of his incapacity to pay for it. In a small number of cases there may have been other reasons (some a proper subject for sociological attention) which led to incomplete or unsatisfactory treatment, but none which could be laid at the door of our profession, and certainly none dependent upon a patient's inability to pay. This is a serious statement made after long deliberation.

What I believe the Briton of twenty-five years hence really will shudder at will be the dogmatic nature of the orders and control of treatment now bureaucratically forced on the profession, for the scientific basis of many of these "standardized" treatments will by then have been shown to be utterly false, if the experience of the past is to be any guide to the future.—I am, etc.,

London, W.1. NORMAN C. LAKE.

Unity in the Profession?

SIR,—In our present situation this is an ideal impossible of realization since there are two opposite interests: (*a*) the general practitioner and specialist group; (*b*) the public health services, pensions services, etc. The latter (*b*) are State officers and their natural inclination must be for a universal State service. They have entered such services because they were attracted to the study of public health or they desired a more regular life than either that of the general practitioner or that of the specialist. We of (*a*) have no quarrel with (*b*) in their choice of work, have collaborated with them for years, and hope to continue to do so.

It is, in my humble opinion, imperative that in the vital issues at stake all of (*b*) should be excluded from our deliberations. They will not help us, but they can hinder us in no small way. We (*a*) are fighting for our ideal—a panel system with a definite income limit, with freedom of medical treatment both for our patients and for ourselves, and no interference from any source. This panel system, as envisaged by the B.M.A., adequately supported, will provide an ideal service for the nation, and what more can the people or the Government ask of us? I repeat that in this fight our activities cannot—they must not—be hindered by those of a different ideology in our ranks. We must be rid of all such. We can fight and, I trust, win our battle.—I am, etc.,

Bradford. DONALD WATSON.

Preventive Medicine

SIR,—Your leading article on "Hours of Employment and Health" (Dec. 26, 1942, p. 756) and the lecture of Prof. J. A. Ryle on the "Science of Health" (p. 745) need to be considered together. You show how the long hours of work adversely affect the health of the workers, and it has long been known that fatigue is the greatest single factor hindering production. Prof. Ryle stresses, as he has done before, the value of preventive medicine.

To allow preventive medicine full scope we have to consider politics and medicine. We know that we can even now, though we frequently fail to do so, prevent many deadly diseases and much ill-health, but Prof. Ryle tells us that "it is becoming more apparent that in the future the emphasis of medicine will be increasingly upon its preventive and protective aspects." This may be true of the future, but what of the present? Can we really say that we have yet passed the stage of palliative medicine, reached that of curative medicine, and see preventive medicine in all its glory just down the road?

Men of great achievement find it difficult to attune their outlook to that of ordinary folk; and while Prof. Ryle knows how elementary is our present knowledge of medicine and how numerous are the diseases we can neither prevent nor cure, the general public, who take a great interest in the medical journals, have not this advantage. From this constant reference to the future position of preventive medicine I am afraid that people may come to believe that the science of medicine has advanced further than is really the case, and it might be in the national interest if it were to be more plainly understood how very limited is the sphere of preventive medicine at present. At the same time political considerations should not be allowed to stand in the way of allowing "preventive medicine" full measure of freedom in its own sphere. Hours and conditions of work in factories urgently need changing. The delivering of uncovered bread is a danger and our milk supplies might receive attention. These things could be done now.—I am, etc.,

New Barnet. JOHN ELAM.

Treatment of Head Injuries

SIR,—Dr. T. Rowland Hill has drawn the attention of your readers to the fact that the recovery of working capacity is only one aspect of medical prognosis. He quotes my statement to the same effect. I am delighted to accept his correction of my nomenclature; his reproach of illogicality, however, seems to go too far.

Dr. Hill emphasizes the importance of the differentiation between traumatic (psychogenic) anxiety and the mental state directly produced by cerebral injury. I fully agree with him and with his statement that this differentiation may be very difficult. Post-traumatic anxiety referring to the accident is comparatively rare after head injury, and it is relatively more common after accidents with no, or with mild, cerebral injury than after severe ones—probably owing to the length and depth of unconsciousness of the latter. Unspecific anxiety symptoms can often be traced back to experiences before the head injury, or to subsequent events (for instance, experiences in hospital), or to circumstances only indirectly connected with the head injury. In practice it is often difficult to assess the exact aetiology. I therefore counted in my study on headache all headaches following head injury, disregarding all, even the most obvious, clues to additional causes, psychological or physical. Ritchie Russell's figures for the occurrence of headache after injury can also be regarded as "post" and not necessarily as "propter." This point must be remembered if one forms an opinion about the frequency and severity of the after-effects. It is worth recalling that A. J. Lewis, comparing post-concussional and other neuroses, found a very similar incidence of symptoms. In effort syndrome, headache and giddiness (those usual post-concussional symptoms) were found in 72% and 78% respectively by P. H. Wood.

Headaches seemed to me the symptom most suitable for a statistical study of the after-effects of head injury, since they are by far the commonest symptom, and I have seen very few cases which complained of post-concussional symptoms but were free from headache.

Dr. Hill begins his examination with the question, "Do you feel the same man you were before the accident, or have you never quite recovered from it?" I, personally, try to refrain from leading questions, and this may account for the difference in our impressions. But I wish to repeat that the figures in my follow-up study on headache are based on direct questions. After some general inquiry about his state of health, each patient who appears in the tables was asked, Did he have headaches or giddiness? And did he sleep well? (Information about his concentration and fatigue was not gathered by direct questioning, but by an inquiry into his occupation or work.)

Jefferson has aptly formulated that we should treat each case of head injury as a potential neurotic. It has been my privilege to carry this suggestion into effect. Thanks to the co-operation of surgeons and neurosurgeons, these cases were treated from the first day with a view to preventing neurotic after-affects. The figures on the occurrence of headache and on the loss of working time may have been influenced by this co-operative effort.—I am, etc.,

London, N.W.7. ERIC GUTTMANN.

Vitamins and Physical Fitness

SIR,—I am criticized by Dr. A. A. Harper and his colleagues (April 17, p. 487) for "quoting only general experience as evidence." in contrast to their own "careful statistical examination." This criticism presumably refers to my observation that their recognition of simultaneous improvement in resistance to infection and gain in physical fitness is opposed to general experience. I had almost written "universal"/not "general," but refrained out of deference to the opinion expressed in their article. Universal experience would, I presume, represent statistics *in excelsis*. The conclusions of Dr. Harper and his colleagues were based upon an experiment conducted upon 69 subjects over a period of 21 weeks. I have before me the report of an experiment undertaken at the request of the Ministry of Health to discover the effect on London school children of taking a daily pill containing 1 mg. of vitamin B_1, 50 mg. of vitamin C, 600 international units of vitamin D, 4,000 international units of vitamin A, 2 mg. of riboflavin, and 20 mg. of nicotinic acid amide. The experimental subjects numbered 455; the work was conducted over a period of seven months. The conclusion was, "No measurable beneficial effect." I am a simple-minded man and I do not see how both these statistical results can be correct.

Dr. Harper and his colleagues direct my attention to the claim of the R.A.F. breath-holding and 40-mm. tests to afford indication of the resolution and power of endurance of the subject. The intention of the medical experts of the R.A.F. is to test the suitability of candidates as pilots. And whatever the rationale and criteria of their procedures their *ex cathedra* pronouncements must be accepted. They test endurance. Endurance of what? Presumably to tolerate the exceedingly unpleasant sensation of asphyxia. This doubtless is an accomplishment of some advantage, and it is not for me in my ignorance of aviation to question its validity as a requisite for the duties of a pilot. But is that "physical fitness"?

Apparently the majority, if not all, of their subjects demonstrated their potential ability as pilots. And all the subjects with whom I have been in contact exhibited unsuitability. Even I, with my ignorance of matters statistical, can see that such a coincidence strains credibility beyond the most generous limits. There must be a better explanation. Can it be that the atmosphere in which the R.A.F. tests are performed must be favourable to the production of that tranquillity which ensures stolidity and stabilization of the nervous system, and that in the ability to create such an atmosphere I am deficient? Is that the conception of "physical fitness" as this term is generally understood? (I have reluctantly again to employ the suspect "generally.")

I venture to assure Dr. Harper and his colleagues that I am well aware that the achievement of athletic prowess depends on many other things besides the general state of nutrition. A good many; some still elusive. But every little helps; and if the administration of vitamins could be shown to increase "physical fitness," even would-be world's champions would not disdain their use. Had Dr. Harper and his colleagues discovered an unequivocal improvement in the post-exercise deceleration test to follow their administration I should have been impressed. But, unfortunately, this was not forthcoming.—I am, etc.,

London, W.1 ADOLPHE ABRAHAMS.

Lupus Erythematosus

SIR,—Although I am primarily responsible, I believe, for the view that lupus erythematosus may be a cutaneous reaction to acute or chronic streptococcal infection,[1] I cannot subscribe to the opinion that this is true of all cases, as Dr. F. Glyn-Hughes and Dr. A. M. Spence suggest in their letter (April 10, p. 460). When I first propounded what has been described as "the streptococcal theory" I was subjected not only to criticism, which was welcome, but also to misrepresentation, both in this country and abroad. In France particularly I was accused of holding the view that lupus erythematosus is always of streptococcal origin. I do not believe this, nor have I ever said it. I am satisfied that in some cases it may be a toxi-tuberculide, and I think that the relative incidence of the streptococcal and tuberculous cases may vary in different countries. I have discussed the whole question elsewhere.[2,3]

By a careful study of the clinical history, a thorough physical examination, a consideration of the type of eruption present, and laboratory and radiological investigations, it is usually possible to decide with some certainty to which group of cases a patient belongs, but I admit that it may be difficult or impossible in some instances. The decision is important from the therapeutic standpoint, for, as I have pointed out,[3,4] the sulphonamide group of drugs, which in my hands has proved of value in many streptococcal cases, has been ineffective, as one might expect, in the tuberculous ones. Conversely, my impression is that injections of gold compounds are more likely to give satisfactory results in the latter than in the former.

In cases suspected of being streptococcal in origin it is important, as Dr. Glyn-Hughes and Dr. Spence indicate, that gross foci of infection should be dealt with before sulphonamide therapy is instituted. I have already stressed[2,3] the susceptibility of many patients with lupus erythematosus to sulphonamides Severe febrile reactions, with temporary exacerbation and extension of the eruption and swelling of the lymphatic glands, are not uncommon, and I have given reasons for distinguishing reactions of this kind from so-called "drug fever." I would repeat the warning I gave then: "It cannot be too strongly emphasized that the indiscriminate use of the sulphonamides is fraught with danger."

The clinical evidence, apart from the positive results with guinea-pig inoculations obtained by several observers, that a tuberculous toxaemia is responsible for the eruption in some instances seems to me incontestable. The following very remarkable and tragic case will serve as an example:

A female child aged 7 was diagnosed as having lupus erythematosus associated with extensive tuberculous cervical adenitis. No family history of tuberculosis obtained. Breast-fed until 9 months old. Skin first affected at the age of 10 months on the malar regions when she was at Folkestone in the summer. The parents observed that the eruption was clearly provoked and aggravated by exposure to sunlight. Until the winter 1940–1 it had always cleared completely during the winter months, only to relapse in summer. In June, 1940, the child had an attack of German measles, which was followed by right-sided cervical adenitis with subsequent abscess formation. The tonsils were first removed, and an operation on the abscess and glands then performed. After the operation the eruption completely disappeared, although the child was lying out of doors and was exposed to sunlight. It gradually returned, and in the following November enlarged glands appeared around the operation scar, the eruption becoming much worse and more extensive.

When I saw her (Feb. 11, 1941) there was typical lupus erythematosus with the bat's wing distribution on the cheeks and nose: elsewhere it was extensive, involving the scalp, neck, ears, back, and arms. There was a large, projecting mass of glands around the scar on the right side of the neck, and there were several palpable ones on the left side and below the chin. I agreed that operative treatment was indicated. A block dissection of the upper deep cervical group of glands on the right side was performed, and some four or five on the left side and two in the submental region were removed. I saw the child again eleven weeks after the operation. The lupus erythematosus had strikingly improved, being much paler and less active everywhere. There were still, however, palpable glands in the neck, the temperature was over 100° F. and the pulse rapid, there were some albuminuria and swelling of the ankles. I thought it probable that the bronchial and abdominal glands were involved. I advised treatment in a sanatorium.

In the following July the physician under whose care she came agreed that she was a case of lupus erythematosus of tuberculous origin, and said she had improved, but still had evening pyrexia He thought that there was abdominal tuberculosis. He has recently informed me that he had heard from the mother that the child died in December, 1941, from, he thought, generalized tuberculosis.

This case is remarkable in several of its features. Lupus erythematosus is rare in young children, and if, as seems likely, the original eruption, which appeared on the cheeks in summer-time from the age of 10 months, was of this nature, the case is unique in my experience. At all events, the fully developed eruption, as I saw it, was unquestionably lupus erythematosus, and an important point is that, although very extensive, it was not of the type usually seen in the so-called lupus erythematosus disseminatus, in which the recent acute lesions resemble those of erythema multiforme and there is often streptococcal septicaemia. On the contrary it was of the indolent hypertrophic type with thick adherent scales and marked follicular hyperkeratosis—the type, in fact, that I usually associate with the tuberculous form of the disease.

---

[1] *Brit. J. Derm Syph.*, 1915, **27**, 365.

[2] *Lancet*, 1929, **2**, 483.

[3] *Brit. J. Derm Syph.*, 1941, **53**, 1, 33.

[4] *Lancet*, 1940, **1**, 583.

To sum up, if one considers the following points one must, I think, logically conclude that in this case the lupus erythematosus was a toxi-tuberculide: (1) the rarity of lupus erythematosus in young children, and the unusual severity and extent of the tuberculous adenitis; (2) the complete but temporary disappearance of the eruption after the first operation on what was at that time presumably the main and primary focus of infection in the glands on the right side of the neck, although the child was freely exposed to sunlight, which previously had always provoked an outbreak; (3) the relapse of the eruption associated with involvement of other glands on both sides of the neck and in the submental region; (4) the striking and more lasting improvement in the eruption after the second and more extensive operation; (5) the fact that the eruption, although very extensive, was not of the kind usually seen in the disseminate form of the disease, many cases of which have a severe and often fatal streptococcal septicaemia.

—I am, etc.,

H. W. BARBER.

Collapse Therapy

SIR,—Dr. Gregory Kayne's warning against the misuse of artificial pneumothorax treatment in pulmonary tuberculosis is timely. The number of cases of chronic empyema, pyopneumothorax, bronchopleural fistula, and gross displacement of the mediastinum and its contents following artificial pneumothorax treatment, that one now meets is appalling. Nor is adhesion section without its risks. At one time, not so long ago, such distinguished practitioners as Mr. Morriston Davies and the late Dr. F. G. Chandler abandoned the procedure, and even now, with the much-improved technique, failures are not unknown.

Unfortunately, one cannot tell beforehand whether any particular A.P. is going to be a success or otherwise; sometimes one obtains a delightfully selective collapse in a very unpromising case, which means that many more have to be attempted than can be persevered with. But, as Dr. Kayne writes, it should be axiomatic that ineffective pneumothoraces should be abandoned at the earliest possible moment.

The public has been so misled by popular propaganda on behalf of physical interference and chemotherapy that patients are now querulous if some such procedure is not undertaken for them. The more drastic the procedure the better pleased the patient; the proud possessor of a Monaldi pump is the envy of the institution. "Am I then to have *no treatment*?" is the disappointed complaint one hears from one's patients when told that such proceedings are unsuitable or unnecessary; and they cannot be convinced that, when all is said and done, the basis of the treatment of tuberculosis remains the slow and methodical building up of the individual's resistance by the sanatorium regime, and that physical interference, while excellent for the cases that need it, always carries additional risks.—I am, etc.,

Chichester. PATRICK HEFFERNAN.

Pulmonary Disease in Miners

SIR,—May I be permitted to comment on the leading article (July 11, 1942, p. 43) entitled "Pulmonary Disease in Miners," When this pathological lung condition was first described by the War Pensions Appeal Board at Auckland, N.Z., in connexion with war gas sequelae (*N. Zealand med. J.*, Dec., 1931, and later issues), we suggested the name "pulmonary degenerative changes", or "P.D.C."

While objections can be urged to both names, it is important that an attempt should be made to convey the various causative factors as well as the associated organic effects that result from the condition. It should be borne in mind that it is still uncertain how many of the associated symptomatic effects are brought about. It is also desirable to envisage the essentially chemo-electrical causation in all types of cases that are due to chemical trauma, be they dissolved gases or dust. I would suggest "chemofibrosis" if the condition is to be approached from the angle of causation in such types. The fact that a somewhat similar degenerative lung condition may arise from constitutional factors should not be overlooked. The merit of "P.D.C." lies in the fact that it can be readily qualified by the addition of words descriptive of either the causation or the resulting symptomatic effects.

While it is likely that impairment of the ciliary defence mechanism is largely responsible for associated infections, the causation of the dyspnoea is uncertain, though it has been narrowed down by later workers. The contribution of Sievers, Enzer, and Becker (New York) would appear to exclude anoxaemia to a large degree. Parkinson and Hoyle (London) have demonstrated the existence of radiological evidence of right heart abnormality. The San Francisco work (Reichert and others) demonstrates the possible importance of the collateral pulmonary circulation in cases where the heart factor does not appear to be dominant. The studies of the Auckland workers demonstrate the raised incidence of lung degenerative changes in a gas-exposed group as compared with other soldiers who could have had no exposure to chemicals. We also described the "right-heart" type of cardiac response to effort and the variation in the "distension-collapse level" in the external jugular vein as an indication of pulmonary artery pressure. The retinal engorgement that occurs is frequently overlooked, and also the fact that the pituitary gland, with its many trophic metabolic functions, could not fail to be involved in some degree. It should be borne in mind that, at present, we have no satisfactory explanation of the hypertrophic digital effects that are not infrequently observed. In view of the authoritative standing of the M.R.C. its further reports will be awaited with considerable interest.

Auckland, N.Z. W. N. ABBOTT.

Gastro-enteritis in Infants

SIR,—In the recent communications on this subject in the *Journal* I have not noticed any reference to infusion into the bone marrow. This method is so simple and effective, and in my experience infusion into a vein of a dehydrated infant so difficult and the subcutaneous route so uncertain, that I thought a note on the method might be useful.

The site of choice in an infant is at the junction of the upper and middle thirds of the superficial surface of the tibia. A Tocantins needle, which is a stout, wide-bore, double hollow needle with a stylet 2½ cm. long, is gently made to penetrate the bone after preliminary infiltration of skin and periosteum with procaine—a sense of feel indicates when the bone has been pierced—the stylet is then removed, and a 1- or 2-c.cm. syringe half full of saline is attached to the inner needle, through which, if properly inserted, bone marrow can be withdrawn into the syringe by working the piston backwards and forwards. The syringe and inner needle are now removed, taking care in doing so that the outer needle remains *in situ* and is filled with saline to prevent an air-lock. An intravenous infusion apparatus containing the fluid to be infused—saline, glucose, or what you wish—which has been got ready beforehand, is immediately attached to the outer needle and the container raised to between 3 and 5 feet and the drip mechanism regulated to 40 drops a minute. It will be found that the fluid runs in quite readily at this speed—a pint can be infused in this way in about 4 hours The needle maintains itself in position without fixing and the limb is lightly splinted.

I have treated a number of cases by this method and not found any difficulty. An infant who died 80 days after infusion by this method showed no damage to the bone or bone marrow at necropsy.—I am, etc.,

Redhill, Surrey. L. J. BARFORD.

Tube Grafts in Cleft Palate

SIR,—As so often happens when diametrically opposite views are strongly expressed, I find that Major M. C. Oldfield and I are not talking about quite the same thing. In his reply (Dec. 12, p. 706) to my letter he speaks of one end of the tube graft being "attached to some part of the upper extremity or chest." Therein I quite agree with him that such a procedure is little short of barbarous in its acute discomfort to the patient. If, however, Major Oldfield would try attaching one end of the tube graft to the inner surface of the upper lip first, before swinging it into the mouth, I think he will come to agree with me that no pain whatever is occasioned the patient and that the method often serves a useful purpose in properly selected cases, both civil and military, and will enable him to effect restorations for certain patients for whom he could otherwise do nothing. Post-operative sedatives are never necessary or even requested, and the whole series of stage operations are done under local anaesthesia.

There is nothing very new or original in the use of tubed pedicle grafts that they should call forth what Wilfred Trotter termed "the most quickly acting antigen to science"—a new idea. They were described, used, and portrayed by Taliacotius (1546-99) exactly in the manner envisaged by Major Oldfield—not, so far as I know, for the palate, but for facial and nose restorations—the intervention of one additional simple stage (to the lip), and what a difference!—I am, etc.,

Wellington, N Z. H. P. PICKERILL.

Mitral Systolic Murmurs

SIR,—Probably every second of every day some doctor somewhere is confronted with a mitral systolic murmur, and he has got to do something, or nothing, about it. That is my excuse for again referring to this subject, so vitally important to both the doctor and the patient. Purely destructive sarcasm such as is contained in Dr. D. S. Lewis's criticism (April 10, p. 459) of my observations on Dr. Evans's article, in which he avoids the issues raised in the rest of my letter and picks out one of a pair of twin postulates indissolubly bound together while refraining from mentioning the other, merely still further fogs the issue and gets us nowhere.

What are these two postulates of Dr. Evans, and how does Dr. Lewis deal with my quotations of them, which the latter says proves my fogged state of mind and accuses me of dwelling in a "*reductio ad absurdum* of my own making"? They are:

1 "When the murmur is decidedly louder in the upright position it is the innocent kind"; and.

2. "*In instances in which a trivial* mitral systolic murmur becomes louder in the reclining posture, *and in which a murmur develops at the base of the heart and particularly in the pulmonary area,* the innocent nature of the murmur can be presumed."

I have italicized the words that Dr. Lewis accuses me of "altering or ignoring," which he says "changes entirely the meaning and significance of the paired quotations, besides disproving the charge of contradiction in terms implied by him." The only alteration I have been guilty of is substituting the word "when" for "in instances in which," and "when" is obviously much shorter and means the same. As to my omissions on which Dr. Lewis lays so much stress, they can only mean this: that if either he or Dr. Evans finds a "trivial" mitral systolic in a patient standing up, and they then lay him down and find that the murmur is louder and that another murmur is superadded, they are at once satisfied that these murmurs are "innocent." Why? It may be so, but I should like to know what causes the murmur and why it is "innocent." It is no good saying that the cause of the murmur is unknown and therefore does not matter. And what is a "trivial" murmur? A "soft" or "barely heard" one? But soft ones are often much more pathologically significant and dangerous than loud harsh ones.

In "M.R.B.1," the guide book for medical boards, that part alluding to "Heart (Diseases of the)," and presumably drawn up by competent cardiologists, says, "In all cases the heart should be examined whilst the man is standing and also whilst he is lying on his left side, otherwise some cardiac murmurs are difficult to detect." So evidently some notice has to be taken of these murmurs. Anybody talking about "innocent" murmurs should drop sarcasm and dogmatism and give his reasons for calling them so by advancing some physical cause for their occurrence. Broadbent mentions one—i.e., "A spurious murmur (mitral systolic) can be produced by compression of the edge of the lung by the ventricular systole." That, at any rate, gets us somewhere.—I am, etc.,

H. S. GASKELL, M.B.

Interstitial Emphysema during Labour

SIR,—Dr. Roger Stanley's description (April 17, p. 477) recalls to my mind a very similar but milder case. Eight years ago my niece, aged 24, was delivered of her first infant without much difficulty. Three hours afterwards her husband called me up, and said that the left side of her face and neck and down on to the thorax was "all swollen up." I asked him to palpate it, and on returning he replied that it "crinkled and crackled." His doctor called in a Queen Charlotte's consultant, who declared that he had never seen the like. My niece had no cough, but for the last two months had had severe albuminuria, and was in consequence kept on a very meagre diet. In about a week all the emphysema had disappeared. No trouble was discovered in the thorax, and since then she has had another child and has had excellent health.

Every endeavour I have made to discover the cause of this disorder has been unavailing. The condition is so rare that I felt that my case should be recorded also.—I am, etc.,

Telford. VAUGHAN PENDRED.

Trichlorethylene Anaesthesia

SIR,—I was much interested to read Dr. Philip Ayre's valuable letter (April 17, p. 489), and fully agree with his conclusions. I would like to suggest a possible answer to the question he poses at the close of his letter—namely, why the respiratory rate increases during trichlorethylene anaesthesia.

I have given trilene on 150 occasions on an open mask on lint as *sole* anaesthetic in operations ranging from tonsillectomy to gastro-enterostomy. This technique is not advisable for general use, but it seemed to afford the most convenient way of observing the effects of this agent uncomplicated by the simultaneous use of other agents such as pentothal, nitrous oxide, etc. Premedication in adults was usually morphine 1/4 gr. and atropine 1/100 gr. There is rarely any overbreathing in stages 1 and 2 of the anaesthesia, and I have only observed excitement, cyanosis, and hyperpnoea in the anaesthetic-resistant type.

The tachypnoea begins when the patient has entered stage 3, plane 1, of anaesthesia, when the greatest concentration of the anaesthetic is being administered to produce saturation. The respirations are *shallow* and rapid, and are often followed by a period of apnoea, which ends spontaneously, as I have seen on several occasions, though I prefer to restart the breathing by gentle compression of the chest. I have seen typical anoxic convulsions at this stage in one case. The pulse remained regular, full, and unchanged in rate during this apnoeic period, and I did not observe cardiac irregularities except on one or two occasions. I did not intubate these patients, but always inserted an oral airway.

When stabilization in stage 3, plane 2, is achieved the rate of respiration usually settles down, but remains about 30 per minute, and, of course, at this stage the quantity of anaesthetic supplied is lessened. I tried giving CO_2 to ward off apnoea, but this only produced deep, rapid respirations, and did not prevent the onset of apnoea, which was longer in duration when it did occur. I then tried administering oxygen in a steady stream under the mask as soon as stage 3, plane 1, was entered, and found that in most cases this prevented the onset of apnoea and kept the respiratory rate within reasonable bounds.

I believe that the explanation of these facts is as follows. When the anaesthetic concentration in the blood and tissues reaches a certain level, a varying degree of histotoxic anoxia ensues. This causes the rapid, *shallow* respiration of oxygen lack, resulting from anoxia of the cells of the respiratory centre. Addition of CO_2 causes increased fatigue of the respiratory muscles, and increases the anoxia. As a result of the tachypnoea, carbon dioxide is washed out, the respiratory stimulus lowered, and apnoea follows and persists until the blood CO_2 rises sufficiently to stimulate the respiratory centre and restart breathing. This should not be waited for, as the spontaneous resumption depends on the basal metabolic rate, the amount of reserve of oxygen, and the state of the cardiovascular system.

This explanation fits in with the fact, which Dr. Ayre emphasizes in his letter, that administration of plenty of O_2 with the trilene will prevent the onset of tachypnoea, and I believe that this should be a routine procedure with this anaesthetic. For administration of 4 litres of oxygen a minute, as Dr. Ayre recommends, a Coxeter's dry flowmeter would be required, since the rotameter type is calibrated to deliver only 2 litres a minute.—I am, etc.,

Nelson, Lancs. T. D. CULBERT.

Foot-and-Mouth Disease in Man

SIR,—In reply to Dr. I. C. Monro (April 24, p. 520) I can add to my remarks in my letter of March 6 only that convalescence was not complete for 3 to 4 weeks, the lesions resolving slowly but ultimately clearing up. There was no evidence of nail involvement or otherwise on the patient's body.

The diagnosis was not absolute, and without laboratory support this can only be tentative. But I, personally, have never seen a Vincent's infection with anything quite like the appearance of the lesions in this patient's mouth, or even, more notably, the intense, peculiarly penetrating and sickly sweet smell which dominated all other signs.—I am, etc.,

Dingwall. KENNETH I. E. MACLEOD.

Chemical Luminescence Test for Blood

SIR,—With reference to the article by Dr. John McGrath entitled "The Chemical Luminescence Test for Blood" in your issue of Aug. 8, 1942 (p. 156), it should be pointed out that the claim that the test is specific for blood is not supported by facts. To give only one example, copper salts give a positive test. Verdigris, which is often a constituent of paints, gives even greater luminescence than blood stains. The test appears to be of a similar nature to the benzidine test and the guaiacum test, and does not appear to have any particular advantage over them in the routine examination of blood stains. It has further the disadvantage that the test has to be carried out in the dark, and does not facilitate the disposal of large numbers of cases.—We are, etc.,

S. RAJAGOPAL NAIDU,
Chemical Examiner to Govt. of Madras.
Madras N. PITCHANDI,
Assistant to Chemical Examiner.

Research in the Continental Clinic

SIR,—The excellent paper by Dr. F. M. R. Walshe on "Strategy and Tactics in Research" (April 17, p. 467) gives ample scope for thought on the future reorganization of medical research. I agree fully with most of his ideas, particularly with his emphasis on the importance of "true discoverers" and their schools of thought (e.g., Sherrington, Hopkins, and Lewis). Perhaps I may add to the discussion by referring briefly to the way research was conducted on the Continent, where a great deal of medical research was done in the clinics, and the contact with the theoretical institutes was very close.

As a rule the head of a university clinic, especially in the more important centres of medicine such as Berlin, Vienna, Munich, Heidelberg, etc., was a man of world reputation with an outstanding record of scientific research. His position was somewhat like that of the superintendent in a municipal hospital in London, but he had perfect liberty in the choice of his assistants, in his research, and in the use of his budget. In some places, as in Berlin, he was even free to choose the patients from the pool of the distribution centre for admission to the clinic, according to research and teaching requirements. There was always a great number of applicants and a waiting list for assistants in these clinics, and he could choose the most suitable. In order to secure a high standard of research work most clinicians made it a condition that their assistants, after their qualifying examination and their practical year, had had a theoretical training of at least 2 years as assistants in either an institute for biochemistry, physics, bacteriology, or physiology, or, in the case of surgeons, in anatomy or pathology.

After 4 years in the clinic the assistant became eligible as lecturer if his research work satisfied the faculty, and after another period of 4 years or more he could be appointed assistant professor (extraordinary professor) by the Ministry of Education on recommendation by his chief or other members of the faculty holding a chair. After that they were considered potential successors and heirs to the throne (chair). They either carried on the school of thought of their teacher or became themselves founders of a new tradition. Not much was thought of those who had not their particular "line of research," which was carried on over a long period. This tradition gave opportunities to follow up an idea over a long period, even through more than one generation. The younger men had the benefit of critical control by experienced research workers, who gave them technical advice and critical judgment, and as a rule had a sufficient knowledge of relevant literature and its value. The chief of the clinic had the ambition to be a benevolent godfather to his assistants' work.

The dual control by faculty and State did not abolish, but restricted, abuses such as favouritism for sons, in-laws, or members of influential feudal student clubs. Religious rather than racial prejudice played a part, in some Catholic States working against Protestants, and vice versa, in both cases against the members of the Jewish faith community. Paul Ehrlich, who remained a Jew, never became appointed to a chair. The physicist, Prof. Lenard in Heidelberg, a baptized Hungarian Jew, not only held the chair but became an honorary Aryan and author of a book on German physics under Nazi rule.

Industrialists were often far-sighted enough to support research without expecting quick returns, and contributed not only by money, but also by placing their experience, assistants, or equipment at the disposal of a research worker. I mention the example of A. v. Weinberg (I.G. Farben), the close friend and supporter of Ehrlich.

Fate has placed me on the wrong side of the fence, and it may be that adverse experiences have influenced my views on essentials for successful research. They are: (1) Life-long or long-term appointments, grants, and facilities in departments (clinical and/or theoretical) of their own to be given to older and experienced research workers who have proved their ability by research achievements. They should have full freedom in the choice of their research, of their collaborators, and in the use of their budget. (2) Appointments or grants to be given to suitable younger research workers for periods of at least 3 to 5 years in order to enable them to perform a piece of work under the guidance of an experienced man of Group 1 in either clinics or theoretical institutes, or both. They could either assist in the work of their chief or do independent work under the guidance of his criticism and advice. (3) Chances of promotion from Group 2 to Group 1 for all suitable research workers. (4) Opportunities for research should be given to doctors and scientists according to ability and success *only*, and the choice should be independent of and not be influenced by prejudice and privilege.

Those who are in the position to make the choice should always realize that theirs is a responsibility not only to the nation but to mankind. There are still scientists who, like Archimedes, would rather have their head chopped off by an ignorant barbarian than abandon their thoughts and problems.—I am, etc.,

London, W.1. E. M. FRAENKEL.

Marching and Standing

SIR,—When long marches are such an important part of the training of the soldier, I think it worth while to publish the following marching tip. It was shown to me 50 years ago by a very good pedestrian, and I have used it on many a strenuous march in many parts of the world.

On the march, as soon as leg weariness is felt or, better, before this, and afterwards about every five miles, lie on the back and elevate the legs to nearly a right-angle with the body, resting the heels and only the heels against any available object. The legs must not be held up by muscular effort: keep them elevated for four minutes. It is best to time this with a watch. Time seems long under these circumstances and is apt to be cut short. There is no use in prolonging the time as the circulation has then re-established itself. The effect is quite remarkable. One's boots seem to have got a size larger and the toes can be moved freely inside the boot. On standing up all signs of leg-weariness have disappeared and the feet feel delightfully light and comfortable. Of course, this is only the way in which a limb is emptied of blood by the surgeon. It would seem that with the upright posture and prolonged walking the heart action and the drive of the leg muscles are not sufficient to maintain a thoroughly satisfactory circulation in the feet. The upright posture is a recent acquisition of *Homo sapiens*. I have never known anyone who was not surprised and delighted at the result of this procedure. I believe it is worth ten miles a day to anyone who adopts it. I think, too, that the relief of congestion has a great influence in preventing sore feet and blisters.

In Mesopotamia, where on desert marches there was nothing to rest the feet against, I evolved a drill. The men lay down in two rows, feet to feet, and then rested their heels against those of their opposite numbers. I think that this is a measure which might find useful application in the case of shop-girls and all who have much standing to do. I believe it would result in much increased efficiency. Standing quite still and so depriving the leg muscles of their pumping action can be very painful. In old days in the Navy a man was, as a punishment, made to stand on a chalked circle.—I am, etc.,

Taynuilt, Argyll. P. F. CHAPMAN.

Artificial Respiration

SIR,—I cannot agree with two points in Dr. E. J. Thomson's letter (April 17, p. 490), in which he says that in artificial respiration (1) atmospheric pressure is the force we are dealing with, and (2) the problem is to get air out of the lungs, not in.

1. As we are immersed in the atmosphere it presses equally inside and outside the chest and can in practice be ignored, except, for example, in the "iron lung," in which some of the weight of the air is rhythmically taken off the outside of the chest, causing inspiration.

2. In Schäfer's method inspiration is actually the weak point (not expiration), because it relies on elastic recoil due to the muscle tone of the diaphragm. Tone progressively declines in drowning cases, and when it has quite gone (owing to death of the nerve cells) the lungs contract by their own elasticity and pull the flaccid diaphragm right up so that it becomes useless for artificial respiration by this method. Schäfer made the very natural assumption that when pressure was relaxed the thorax would return to its original volume and thus cause inspiration. This is correct in normal subjects but not, unfortunately, in bad drowning cases. That is one reason why our Naval doctors are now recommending my rocking method (which works by gravity and is independent of muscle tone) in preference to Schäfer's as soon as available. (See *First Aid in the Royal Navy,* just published at 2s. by H.M. Stationery Office.)

Dr. Thomson's other point is that the rocking method would not be available at low tide on shallow beaches such as the Solway. I believe a builder's two-wheel hand-cart (for carrying ladders, etc.) would serve this purpose and be readily transportable for organized bathing, though Schäfer must be kept up till it arrives. But Schäfer's method fails far too often.—I am, etc.,

Hull FRANK C. EVE.

A Nutritious Diet-drink

SIR,—The warnings in your leader on minimum standards of feeding are most timely. It is of little value to state the "rations" that are authorized; the important point is to know the actual rations that are obtained. I would, however, draw attention to the still greater importance of utilizing as food all the rations that are actually received. Owing to the ignorance of English cooks and the convenience of "mass" cooking in canteens and institutions much food value is being wasted.

I have had the opportunity during the last 12 months of having charge of dysentery wards in several mental hospitals. I have found a considerable number of patients suffering from cellulitis of the legs and feet, swellings about the body, unnourished nails and teeth, and other pre-scorbutic symptoms; and this in spite of, on paper, a sufficient supply of root and green vegetables. Over-cooking and use of soda were the two greatest faults in the institution kitchens.

By the co-operation of wise medical superintendents and by the willing fellowship in service of the cookery supervisors I got a "tisane" made daily and issued as a ration in place of tea to all such patients. This preparation received the full vitamins A and C from the vegetables, and the result has proved the value of a diet ration always well known in all the South Continental hospitals. The "tisanes" were made from the vegetables available from day to day. They were chiefly from potatoes, carrots, turnips, cabbage, and some onions, leeks, and celery as and when available. By putting them through the fine mincing machine a valuable salad was also added, made from the hearts of savoys, brussels sprouts, raw carrots, raw turnips, with occasional watercress and onions and celery.—I am, etc.,

London, W 1. JOSIAH OLDFIELD.

Dr. Johnson's Asthma

SIR,—Sir Arthur Hurst's splendid paper on asthma (April 3, p. 403) has dispelled most of my doubts on this controversial subject. I do not think he is quite correct, however, in his reference to Sir John Floyer. He states that Floyer wrote a *Treatise on Asthma* in 1698 and that Dr. Johnson, who was his patient, relates how he "panted on" till his death at the age of 83, thirty-six years later. I doubt very much whether Johnson ever was a patient of Floyer's or even met him. I cannot find any evidence of it in the pages of Boswell; and besides, Johnson did not leave his native Lichfield to try his fortune in London until 1737, three years after Floyer died. At that time he had not emerged from the mists of obscurity, and his impecuniosity was such that the fees for a man of the standing of Floyer would have precluded him from seeking his advice.

The only mention of Floyer by Johnson is in two letters written in the last year of his life in 1784, when he was suffering from attacks of breathlessness which he attributed to asthma. It was natural that he should be interested in a man who was not only an authority on the subject but had suffered from the complaint himself. Here is an extract from the first letter: "My asthma is, I am afraid, constitutional and incurable; but it is only occasional, and, unless it be excited by labour or cold, gives me no molestation, nor does it lay very close siege to life; for Sir John Floyer, whom the physical race consider as an authour of one of the best books upon it, panted on to ninety, as was supposed; and why were we content with supposing a fact so interesting, of a man so conspicuous? because he corrupted, at perhaps seventy or eighty, the register, that he might pass for younger than he was. He was not much less than eighty when, to a man of rank who modestly asked his age, he answered, 'Go, look'; though he was in general a man of civility and elegance." There, in a few sentences, is an entertaining and illuminating pen-picture of Sir John by the great lexicographer himself.

The second extract is from a letter to his physician, Dr. Brocklesby: "I am now looking into Floyer, who lived with his asthma to almost his ninetieth year. His book, by want of order, is obscure; and his asthma, I think, not of the same kind with mine."

Dr. Johnson was quite right in surmising that he was not a true asthmatic. He was obviously suffering from myocardial insufficiency with progressive heart failure.—I am, etc.,

Leeds. R. G. MELVIN.

Houses to Live In

SIR,—So 10,000 flat-roofed farm-workers' cottages are to be built with concrete floors, walls, ceilings, and roofs! Any rural practitioner in the West Country knows how even good ordinary houses will "sweat" with our quick changes of humidity and how discouraging is the treatment of the rheumatic cottager living on a stone ground floor. For months in the year these dank rheumatism traps will not have a dry clout in them: a tent would be much healthier. And they are being sponsored by a Ministry of Health! Truly we are becoming nose-led by a city-minded bureaucracy.

The all "stone" method of construction can be made to give excellent results in North Africa or, centrally heated, in a dry drained town, but is totally unsuited to the coastal and moorland areas of Great Britain.—I am, etc.,

Newton Ferrers, S. Devon. W. F. BENSTED-SMITH.

Chairs of Child Health

SIR,—I observe in the issue of the *Journal* of April 17 a statement, in connexion with the inaugural lecture on "The Health of the Child" to be given in Newcastle by Prof. Spence as first holder of the Chair of Child Health in the University of Durham, that Durham is the first university in the kingdom to establish such a chair. The date of the institution of such chairs is of small moment so long as they *are* instituted, but I think it should be pointed out that a Chair of Child Life and Health has been in existence in this university since 1931.—I am, etc.,

SYDNEY SMITH,
Dean of the Faculty of Medicine,
University of Edinburgh.

Obituary

WARRINGTON YORKE, M.D., F.R.S.

Professor of Tropical Medicine, University of Liverpool

Warrington Yorke, who died on April 24, was the son of the late Rev. H. Lefroy Yorke, and was born at Lancaster in 1883. He attended University School, Southport, and Epworth College, Rhyl, and studied medicine at the University of Liverpool in the time of Sherrington, Paul, and Rubert Boyce. He obtained the degrees of M.B., Ch.B. in 1905, followed by that of M.D. in 1907; in 1929 he became M.R.C.P., followed by the Fellowship in 1934.

[*Vandyk*

Very early in his medical career he joined the School of Tropical Medicine because the study of diseases of the Tropics attracted him. In 1907 he went to Nyasaland on a two-years commission to study blackwater fever. He was appointed Director of the Runcorn Research Laboratory of the Liverpool School in 1909. During 1911-12 he was in Northern Rhodesia on the British South Africa Company's Sleeping Sickness Commission, and soon after the commencement of the last war in 1914 he was in Sierra Leone investigating sleeping sickness. He was appointed Walter Myers Professor of Parasitology in 1914 and he held this post until 1929, when he was made Alfred Jones Professor of Tropical Medicine. During the period 1920-9 he acted as honorary assistant physician and then was appointed honorary physician for tropical diseases in the Liverpool Royal Infirmary. From 1937 he served as examiner in tropical medicine and hygiene to the Conjoint Board in London.

Besides taking part in and leading several scientific expeditions to the Tropics, Yorke was commissioned to travel widely in connexion with projects designed to disseminate knowledge of medical progress in tropical countries. Thus he went to Antwerp to supervise the tropical health exhibit at the International Colonial and Maritime Exhibition; to Buenos Aires for the British Empire Trade Exhibition; to Dresden for the International Hygiene Exhibition. In 1939, and again in 1942, he went to the United States of America, the latter journey being undertaken on behalf of the Medical Research Council and the Ministry of Supply. During the latter part of his career he was especially interested in the advance of chemotherapy, and to this branch of research he made numerous scientific contributions of an original character and of a high order. He was a member of the Tropical Research Committee of the Medical Research Council, and also of the Chemotherapeutic Research Committee of Imperial Chemical Industries. Over and above this great range of work he found time to engage in many other activities. He was chairman of two public schools—Penrhos College and Birkenhead School—and was also chairman of Greenings and Sons Limited and two affiliated companies, and on the board of the West African Drug Company.

Warrington Yorke's outstanding work in tropical medicine earned him wide recognition abroad, and he was a member of numerous foreign scientific bodies. His reputation was recognized by invitations to address many foreign societies, and the engagements which he fulfilled in Germany, Italy, and America represent only the few which he found it possible to accept. In 1925 the Chalmers Memorial Gold Medal of the Royal Society of Tropical Medicine and Hygiene was conferred on him for his conspicuous services to the cause of tropical medicine, and in the year 1932 he was elected a Fellow of the Royal Society, which appointed him Croonian Lecturer this year.

The Alfred Jones Professorship of Tropical Medicine which Yorke held is of historic interest in the annals of the Liverpool School. The chair was established in 1902 and the first occupant was Ronald Ross, who held it until 1913. His successor was J. W. W. Stephens, and he, in 1929, was succeeded by Yorke, who occupied the chair until the time of his death. The duties of the Professor of Tropical Medicine have become almost yearly more onerous as a result of the progress of research and the extension of the ground to be covered. It was fortunate indeed that Yorke's early training and wide experience qualified him admirably not only to fulfil the duties of this chair with great distinction but also to add very greatly by his own original research to our fuller understanding of many important tropical diseases. At the Annual Meeting of the British Medical Association in 1934 he was president of the Section of Tropical Diseases.

In the last war Yorke served in the R.A.M.C. and was stationed in Malta; during this war he was engaged, up to within a short time of his death, in conducting courses for Service medical officers going abroad to tropical countries. He married in 1916 Elizabeth Annie Greening, and they had two children. He is survived by his wife, one son, now unfortunately a prisoner in Japanese hands, and one daughter.

D. B. BLACKLOCK.

Sir **PHILIP MANSON-BAHR** writes:

Warrington Yorke stood for accuracy and truth. What he wanted were facts and proofs, and it must be admitted that he generally provided both. In manner he was direct, alert, questioning, and vivacious. It therefore followed that he abhorred shams and shibboleths. He preserved a sane, analytical, and healthy attitude to medical research in general and to tropical medicine in particular. It is therefore not too much to claim that to Continental workers he typified the spirit of British research, and his reputation thereby became world-wide. In tropical literature his critical reviews were a joy to read and digest, and in every case they constituted a real lasting contribution. In teaching he was clear, didactic, practical, and instructive; in research original, inventive, resolute. He went straight for his objective and never hesitated or swerved in his course till results had been obtained. In tropical medicine Yorke typified an epoch, and his loss will be mourned not only by the School of Tropical Medicine of which he was the fountain-head and moving spirit, but also by scientific circles all the world over.

We regret to announce the death at Fareham of Surgeon Captain **JAMES CAMPBELL BRINGAN**, R.N. (ret.), who had long specialized in eye diseases, first while serving in the Navy and afterwards in civil life at Portsmouth. He studied medicine at Glasgow University, graduating M.B., Ch.B. with honours in surgery in 1902. During the last war he was appointed a Chevalier of the Order of the Redeemer of Greece, a Chevalier of the Crown of Italy, and received the silver medal of the Italian Red Cross. Before his retirement from the Navy he had been ophthalmic surgeon to the R.N. Hospitals at Malta and at Haslar, and to the R.N. Depot, Bournemouth. He became ophthalmic surgeon to the Portsmouth Eye and Ear Hospital and to St. Mary's Hospital, Bournemouth, and was a member of the Ophthalmological Society of the United Kingdom. He was elected chairman of the Portsmouth Division of the B.M.A. three years ago.

We regret to announce the death on April 6 of Dr. **HAROLD SNAPE**, late of Pendleton, Lancs. He was born in Manchester on Aug. 16, 1875, son of Alderman Joseph Snape, J.P., and from Manchester Grammar School went to Owens College, graduating M.B., Ch.B. of the Victoria University with first-class honours in 1899. In the last war he served, with the rank of captain, R.A.M.C., as anaesthetist to the 2nd Western General Hospital, Salford; after demobilization he became examining medical officer under the Ministry of Pensions and held a number of posts as medical referee to assurance companies. During his years of active practice Dr. Snape had been anaesthetist to the Manchester Children's Hospital, honorary physician to the Pendleton Dispensary Branch of the Salford Royal Hospital, and visiting surgeon to the Southport Infirmary. He was an officer of the Order of the Hospital of St. John of Jerusalem and an honorary life member of the St. John Ambulance Association. He joined the B.M.A. in 1901 and contributed several papers on anaesthesia to these columns.

We regret to announce the death in April by enemy action of Dr. **ARTHUR ARBUTHNOT STRATON** of Newport, Isle of Wight, who was honorary surgeon to the Royal Isle of Wight County Hospital at Ryde and consulting surgeon to H.M. Prison.

Parkhurst. Dr. Straton studied medicine at St. Mary's Hospital, graduating M.B., B.S.Lond. in 1907 and winning the gold medal at the M.D. examination in 1913. He also took the F.R.C.S.Ed. diploma. Before settling in private practice he had been resident surgical officer at the Wolverhampton General Hospital, senior house-surgeon at the Royal Sussex County Hospital, Brighton, and resident obstetrical officer at St. Mary's. During the last war he served as temporary captain, R.A.M.C. He had been a member of the B.M.A. since 1911. A warm tribute has been paid in the local press to Dr. Straton's devotion to duty, his kindness and generosity, his robust common sense and ripe wisdom. A former colleague writes: During the years that I lived in the Isle of Wight Dr. Straton was my near neighbour and an intimate friend, and I had a high opinion of him as a family doctor. He will be sorely missed, for he was in the forefront of his profession both as a physician and a surgeon.

We regret to announce the death on April 17 of Dr. **HENRY BUIST**, one of the best-known medical practitioners in Dundee. He had been a member of the B.M.A. for 40 years, was president of the Dundee Branch in 1926-7, and had also served as president of the Forfarshire Medical Association. Dr. Buist was a native of Dundee, and before taking up the study of medicine at Edinburgh was for some little time a schoolmaster. He graduated M.B., Ch.B. in 1901 and proceeded M.D. in 1928; he was an honorary life member of the St. Andrew Ambulance Association and a J.P. for the city of Dundee.

The death is announced of Prof. **PAUL BÉGOUIN**, formerly professor of surgery at Bordeaux University and president of the French Surgical Congress in 1927. Most of his publications deal with gynaecology.

The Services

Surg. Cmdr. R. L. Stubbs, R.N.V.R., has been awarded the R.N.V.R. Officers' Decoration.

Temp. Surg. Lieut. C. B. Holland, R.N.V.R., has been awarded the D.S.C., and Temp. Surg. Lieut. J. L. B. MacFarlane, R.N.V.R., has been mentioned in dispatches (posthumously) for bravery in Northern Waters.

Capt. (Temp. Major) T. R. Wilson, R.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in North Africa.

Capt. E. T. Gilbert, R.A.M.C., has been appointed O.B.E. (Military Division) in recognition of gallant and distinguished services in the field.

A *Supplement* to the *London Gazette* dated April 20 announces the award of the Albert Medal in Gold to Temp. Surg. Lieut. M. J. Clow, R.N.V.R., for gallantry in saving life at sea. The announcement reads as follows: "Surg. Lieut. Clow was between decks when H.M.S. *Ibis* was hit and badly damaged. Wounded men were brought to him in the sick bay, among them an engine-room artificer badly burnt about the arm. Surg. Lieut. Clow gave him an injection of morphine, and, as the ship was now sinking, helped the man up the ladder and out on to the upper deck. As the man had no life-belt he put his own on him. Then he got him into the water, and made sure he was free of the ship before he himself abandoned it. In doing this Surg. Lieut. Clow became entangled in the rigging and was taken down some way before he got clear. He then swam for three hours without a life-belt before he was picked up."

The *London Gazette* announces the posthumous award of the Albert Medal to William Chisholm, M.B., ship surgeon. The announcement reads as follows: "The ship in which Mr. Chisholm was serving was torpedoed in darkness and immediately began to sink. A fire broke out, which enveloped the bridge in flames, and orders were given to abandon the vessel. She sank within eight minutes. One of the senior officers, who was on the bridge, was badly injured. He was taken to the surgery, where Mr. Chisholm immediately attended to him, and afterwards, as he was helpless, helped him to the deck in order to get him away from the sinking ship. Mr. Chisholm's efforts, however, were unsuccessful and neither he nor the officer was seen again. Although the ship was sinking rapidly, Mr. Chisholm remained and deliberately sacrificed his chance of safety in a gallant attempt to save the life of another."

CASUALTIES IN THE MEDICAL SERVICES

Previously reported Prisoner of War, now reported Wounded and Prisoner of War.—War Subs. Capt. W. E. G. Bradford, R.A.M.C., Capt. A. E. Brewer, R.A.M.C., War Subs. Capt. J. K. Drucquer, R.A.M.C.

Universities and Colleges

UNIVERSITY OF OXFORD

Radcliffe Scholarship in Pharmacology, 1943.—This is awarded by the Master and Fellows of University College on the nomination of the Professor of Pharmacology. Candidates must have taken the pharmacology course in Oxford and have passed the examination in pharmacology and principles of therapeutics either in December, 1942, or June, 1943. A special examination in pharmacology for the scholarship will be held in the Department of Pharmacology on Tuesday, July 6, at 10 a.m. Candidates should be prepared to answer questions on pharmacological methods and biological standardization. They may be examined orally as well as by written paper. Those wishing to enter for the examination should send their names to the Department by 12 noon on July 5.

UNIVERSITY OF LONDON

The official *University of London Gazette* reports that regulations for the M.D. and M.S. examinations have been amended by the addition of the following after the reference to the essay: "The essay must be satisfactory as regards literary presentation as well as in other respects." During the war an additional M.B., B.S. examination will be held early in February, which means the holding of this examination three times a year—namely, February, April, and October.

The Senate has appointed a special committee to report on the question of providing further facilities for the medical education of women in London, and on the procedure to be adopted for the provision of such additional facilities.

Mr. George H. Macnab, M.B., F.R.C.S., has been appointed Dean of Westminster Medical School in succession to Sir Adolphe Abrahams, who has retired.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examination indicated:

THIRD M.B., CH.B.—*Pathology and Bacteriology*: S. S. Epstein, G. V. Feldman, Margaret Hedley, Marion B. T. McIntosh, T. M. Martin, Nancy B. Penney, J. A. Shrigley.

Medical Notes in Parliament

Medical Inspection by Women Doctors

Mr. BELLENGER on April 20 condemned the routine medical examination of men in the Army by women medical officers. Dr. MORGAN said the woman medical officer had her duty to do and did it. She had no emotional reaction. About 2% of males and females did not like medical examination by people of the opposite sex.

Mr. ARTHUR HENDERSON said the nation owed gratitude to the women doctors, who to-day rendered most important service. The Army now had a large number of mixed regiments of anti-aircraft artillery, and required women doctors to cater for the needs of women serving in them. The problem did not exist in the Navy or in the R.A.F. These routine medical inspections were designed mainly to detect cases of skin disease or infestation, and had been carried out as a routine on all personnel returned from or proceeding on leave and when men were transferred from one unit to another in the United Kingdom. In future such inspections would be made only when the medical officer in charge of troops or the senior administrative medical officer considered them necessary. They were only required when cases were suspected in a unit and the sufferers were not reporting sick. The inspections had hitherto been known as "F.F.I."—free from infection. In future they were to be called "health inspections," and soldiers and auxiliaries would have the right to be examined by medical officers of their own sex. If this was not immediately possible the full examination would be postponed. In the interim a partial examination would be made at which men would be stripped to the waist and women would wear the equivalent of a bathing costume. At all inspections a third person of the same sex would be present. It was proposed to introduce, so far as possible, the atmosphere of the clinic rather than that of a parade.

Nurses in Scotland

Mr. WATT asked on April 20 whether a Nurses Bill would be introduced for Scotland. Mr. JOHNSTON replied that the Scots committee, presided over by Lord Alness, took views on some aspects of the problem of State recognition of assistant nurses which were divergent from those adopted in England by the Athlone Committee. He was endeavouring to see how far it was possible to bridge the differences before formulating a Bill for Scotland.

Answering Mrs. Hardie on the same date Mr. JOHNSTON said the Scottish Nurses' Salaries Committee had made recommendations regarding the salaries of nurses employed in general hospitals other than approved training schools, and in fever, sick children's, and tuberculosis hospitals, and on the conditions of nursing employment generally. All matters remitted to the committee had been covered with the exception of superannuation and questions relating to assistant nurses and nurses employed in public assistance institutions and mental hospitals. The report was presented to Parliament and copies were available. Mr. Johnston added that he was communicating with local authorities and voluntary hospitals commending the recommendation for adoption.

Fitness Centre at Gleneagles

Mr. JOHNSTON stated on April 20 that after consultation with the Minister of Fuel and Power he had appointed a consultative committee, under the chairmanship of Sir Robert Bruce, consisting of five members nominated by the miners' organizations, five nominated by the mine-owners' associations, one from the Ministry of Fuel and Power, and one from the Ministry of Labour and National Service: (*a*) to assist in ensuring that the benefits of the fitness centre at Gleneagles Hospital were recognized throughout the mining industry in Scotland, and that the fullest advantage was taken of them; (*b*) to assist in the re-employment of patients treated at the centre; and (*c*) to advise on non-medical matters affecting the welfare of patients treated at the centre.

Food Inspection

Mr. ERNEST BROWN, replying on April 20 to Sir William Jenkins, said a communication was sent to local authorities in the course of last year impressing upon them the need for taking all practicable steps to secure the due discharge of the duties of inspection imposed upon them by the Food and Drugs Act, 1938, especially in relation to cleanliness in production, treatment, and distribution of milk. This service was subject to the exigencies of the man-power situation, but arrangements had been made by which sanitary inspectors would not be recruited for military service except in special cases in which their professional qualifications were required in the armed Forces.

Minister of Health on Local Authorities

Mr. ERNEST BROWN addressed the Conservative M.P.s' Social Services Committee at the House of Commons on April 20. He said there was no increase in infectious disease; his Department was collecting information about the results of Regulation 33B on the incidence of venereal disease. The Government recognized the association of environmental conditions with the state of public health, and housing proposals were in preparation. Mr. Brown said he was consulting all interests concerned on the future of the health services. Health and medical services must continue to be worked through local authorities, but adjustments were required. Local authorities hated regional control, and it would be necessary, pending local government reform, to deal with the existing major local authorities, with adaptations. He wished to give as great a scope as possible to the smaller local authorities, who were responsible now for infectious diseases hospitals and were keen on their maternity and child welfare duties. Parliament should build on these. In hospitals there must be regional grouping. He hoped to issue a White Paper on the future of the hospitals. Mr. Brown added an assurance that he was determined to maintain the voluntary hospitals and the right of private medical practice.

Compensation for Practices

Mr. MCENTEE inquired on April 22 whether, in the re-organization of the National Medical Service, it was proposed to compensate doctors for capital invested in purchasing practices and premises used for professional purposes. Mr. BROWN said compensation for loss of value of practices would certainly be one of the subjects with which his proposals would deal.

Financial Help for Tuberculous Persons

Mr. PRITT inquired on April 22 whether the attention of Mr. Brown had been called to an article by Sir Wilson Jameson in *Current Affairs*, No. 37, of Feb. 13, 1943, entitled "National Health"; what special financial help was now being given to sufferers from tuberculosis to meet cases where treatment was put off or stopped for financial reasons; and how much had already been paid out under this head to the latest date for which figures were available. Mr. BROWN said he had seen this article. It had reference to arrangements which were in preparation at the time of its writing. These were not yet in actual operation, but the details had been worked out in consultation with medical experts and representatives of local authorities. A circular and memoranda containing detailed guidance for the local authorities by whom the allowances were to be administered would be issued shortly.

Medical and Ancillary Man-power

On April 22 Sir ROBERT GOWER asked the present number available, respectively, in Great Britain of qualified doctors, pharmacists, opticians, nurses, and other persons concerned in the provision of services or equipment connected with the health of the people. Mr. BROWN gave the following approximate figures:

Registered medical practitioners (excluding N. Ireland) in civil practice or in the Forces	49,100
State-registered nurses (on Register for England and Wales) .	99,590
Qualified pharmacists (excluding N Ireland) . . .	25,150
Opticians (ophthalmic and dispensing, excluding N. Ireland)	6,270

"Relieving the G.P."

Sir ROBERT GOWER asked Mr. Brown on April 22 whether, to make the maximum effective use of the services of available doctors in implementing the Beveridge report, he would institute an investigation into the extent to which doctors could be relieved of routine work by pharmacists in relation to dispensing and carrying out various tests, by qualified opticians in relation to sight-testing, and by increased numbers of qualified nurses both for visiting patients and for assisting in surgery work. Mr. BROWN answered that he intended to consider possibilities of relief of this kind at the appropriate stage of the preparation of his proposals.

Pensions Appeal Tribunals

Sir WALTER WOMERSLEY announced on April 22 that the Government had decided that arrangements should now proceed for setting up independent tribunals to hear appeals from all classes of claimants whose title to compensation was rejected under any one of the various war pension schemes administered by the Ministry of Pensions. Each tribunal would include a legal chairman, a doctor, and a member of the service or class covered by the scheme under which the claim was made. It was the intention to establish 9 tribunals to begin with. These would sit at various centres for the convenience of appellants. Their number would be increased as found practicable, but owing to the difficulty which still existed in obtaining the full personnel required the increase could only be gradual. Legislation would be introduced as soon as possible after the House resumed its sittings. Active steps were being taken to complete preparations for the tribunals to begin their work with the least possible delay.

Nurses Bill

On April 20 the House of Lords took the Committee stage of the Nurses Bill. Lord HORDER moved to insert a new clause to provide that any person should be liable to summary conviction if, knowing that some other person was not registered or enrolled, he made any statement or did any act calculated to suggest the contrary. Lord Horder said that as the Bill stood it was not an offence for a third person, not the nurse herself or an agency, to represent a woman falsely as having qualifications. Lord SNELL accepted the amendment and the Committee stage concluded.

The Nurses Bill was reported in the House of Lords on April 21 without further amendment and was read a third time. Lord KEYES and Lord CHATFIELD repeated the request that naval pensioners with long experience in naval hospitals and in sick-bays of ships should be entitled to the designation of State-registered nurses. Lord Keyes understood that under the Bill these men would be classed as assistant nurses. Lord SNELL said these remarks would be conveyed to the Minister of Health.

On April 22 the Nurses Act received the Royal Assent.

Ministry of Health Report.—Mr. Ernest Brown hopes to publish in three months a summary report on the work of the Ministry of Health.

Notes in Brief

Mr. Ernest Brown states that the Crown has not undertaken to bear the responsibility for costs and damages in the event of a claim being made against a special practitioner giving compulsory treatment under Regulation 33B.

The Minister of Health is advised that it has not been possible to establish the causes of outbreaks of epidemic catarrhal jaundice in this and other countries. A special study of this disease is being made under the auspices of the Medical Research Council.

Sir James Grigg told Mr. Bellenger on April 6 that a soldier might be compelled to be medically examined whether the examination was carried out by a male or a female doctor. He emphasized that he answered a question on the legality and not on the expediency of such examination.

No. 15

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 17.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Puerperal fever is included with pyrexia, except in London (administrative county).

‡ Includes paratyphoid A and B for Northern Ireland.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week scarlet fever notifications rose by 65, while those of measles and acute pneumonia fell by 1,324 and 151 respectively. The decline in scarlet fever occurred in the South, especially in London, 36. Small rises, the greatest being Lancashire 31, occurred elsewhere.

Notifications of acute pneumonia fell in Durham by 41, Lancashire 34, and Essex 32, but only small fluctuations were reported in other counties.

There were 10 fewer cases of whooping-cough than in the preceding week. The largest variations were rises in Yorks West Riding 26 and Middlesex 23, and a drop of 31 in London.

The incidence of measles fell mainly in Derbyshire by 289, Yorks West Riding 272, Gloucestershire 217, Devonshire 181, Durham 122, Essex 129. The counties reporting the largest rises were Suffolk by 155, Staffordshire 148, Worcestershire 96, Bedfordshire 87.

No further cases of dysentery were reported from Cheltenham M.B., where there was a large outbreak in the preceding week, but 9 cases were reported in Bristol C.B. 7 and Thornbury R.D. 2. The highest totals were Essex 18 (Ilford M.B. 13), and Yorks West Riding 20 (Dewsbury C.B. 19).

In *Scotland* there was an increase of 16 in the incidence of dysentery and a drop of 105 for measles. Cases of dysentery were reported from twelve areas, the largest centre of infection being that of the city of Aberdeen, 8 cases. The fall in the incidence of measles did not extend to the western area, where 527 cases were recorded, compared with 523 in the preceding week. The largest declines were those of the cities of Dundee 59 and Edinburgh 40.

In *Eire* the rise in the notifications of diphtheria was due to the experience of Dublin, where 40 cases were recorded.

In *Northern Ireland* there were 227 fewer notifications of measles. Only one case was reported in Lisnaskea R.D., compared with 207 in the previous week.

The Week Ending April 24

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,770, whooping-cough 1,827, diphtheria 710, measles 13,490, acute pneumonia 866, cerebrospinal fever 83, dysentery 69, paratyphoid 5, typhoid 3.

Medical News

The Harveian lecture will be given by Sir Thomas Dunhill on "Short Oesophagus with Thoracic Loculus of the Stomach" at 11, Chandos Street, at 4.30 p.m. on Monday, May 17.

Two Cantor lectures on "Some New Properties of Inorganic Dusts" will be given by Prof. H. V. A. Briscoe, D.Sc., before the Royal Society of Arts, John Adam Street, Adelphi, W.C., on May 17 and 24, at 1.45 p.m.

Prof. G. Grey Turner will deliver the George Haliburton Hume memorial lectures in Newcastle-upon-Tyne at the meetings of the Newcastle and Northern Counties Medical Society on May 20 and 27, at 4.30 p.m., at the Royal Victoria Infirmary. His subject is "The Management of Injuries and Diseases of the Oesophagus."

A meeting of the Faculty of Radiologists will be held at the R.S.M., 1, Wimpole Street, W., on Saturday, May 22, at 11 a.m., when Prof. B. W. Windeyer will deliver the Skinner lecture on "Malignant Tumours of the Upper Jaw." The lecture is open to all members of the medical profession.

At a meeting of the Illuminating Engineering Society on Tuesday, May 11, in the Hall of the Institution of Mechanical Engineers (Storey's Gate, St. James's Park, S.W.) an address will be given at 5 p.m. on "Light and Vision" by Sir John H. Parsons, F.R.S., F.R.C.S. Tickets of admission may be had from the Illuminating Engineering Society, 32, Victoria Street, S.W.1.

The Socialist Medical Association is holding a health workers' convention on Sunday, May 16, at 5 p.m., in the Large Conway Hall, Red Lion Square, W.C., under the chairmanship of Mr. Somerville Hastings, F.R.C.S. The speakers will include Dr. H. Joules, Dr. D. Stark Murray, and Dr. Edith Summerskill, M.P.

A conference on wartime nurseries will be held on May 15 at 3 p.m. at B.M.A. House, Tavistock Square, W.C., under the auspices of the National Society of Children's Nurseries, the Nursery Schools Association of Great Britain, and the London Women's Parliament. The main part of the conference will be open for discussion. Applications for tickets should be sent to the Conference Secretary, London Women's Parliament, 24, High Holborn, W.C.1.

The Nutrition Society has arranged a whole-day conference on nutrition in infancy to be held on Saturday, May 22, at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1, beginning at 10.30 a.m., with Prof. L. G. Parsons in the chair. The following papers will be read: (1) "Nutritional Needs in Infancy," by Dr. H. M. M. Mackay; (2) "Recognition of Nutritional Disorders in Infancy," by Wing Commander R. W. B. Ellis; (3) "Treatment of Nutritional Disorders in Infancy," by Dr. A. A. Moncrieff; (4) "Public Health Aspects," by Dr. J. C. Spence and Dr. H. E. Magee. The discussions after the four papers will be opened by Prof. Noah Morris, Dr. S. G. Graham, Dr. J. V. C. Braithwaite, and Mr. F. Le Gros Clark, respectively. Further details of the Nutrition Society can be obtained from the Hon. Secretary, Dr. Leslie Harris, Nutritional Laboratory, Milton Road, Cambridge.

An extraordinary meeting of the Association of Surgeons of Great Britain and Ireland will be held in London on Thursday, July 22, at the Royal College of Surgeons of England, when the following subjects will be discussed: "The Treatment of Burns in the Field and in Hospital," and "The Use and Abuse of Sulphonamide in War." This meeting will be preceded on July 21 by a reception given by the President and Council of the Royal College of Surgeons. The secretaries for the meeting are E. C. Hughes and Philip H. Mitchiner, who will issue full details to Fellows in due course.

The Lord President of the Council has appointed Charles S. Hanes, Ph.D., F.R.S., to be Director of Food Investigation in the Department of Scientific and Industrial Research. Dr. Hanes is at present serving with the Food Mission in North America.

The National Association for the Prevention of Tuberculosis announced on April 6 that, owing to the difficulty in obtaining nursing and domestic staff, the Colony for Boys at Burrow Hill, Frimley, Surrey, will have to be closed in three months' time. This colony has some 80 beds for the treatment and training of tuberculous youths.

A new and limited issue of the *British Pharmacopoeia*, 1932, which has been out of print for some time owing to destruction of copies by enemy action, is now on sale. Copies (21s., or 21s. 9d. including postage) may be obtained from Constable and Co. Ltd., 10, Orange Street, London, W.C.2. Also available are the First Addendum (1936) 5s.; Second Addendum (1940) 2s.; Third Addendum (January, 1941) 3s. 6d.; Fourth Addendum (October, 1941) 5s.; and the Fifth Addendum (1942) 5s.

The issue of the *Schweizerische medizinische Wochenschrift* for Feb. 13 is dedicated to Prof. Ernst Anderes, professor of gynaecology and obstetrics at Zurich University, on the occasion of his 60th birthday.

The British Records Association has issued a memorandum, under the title *Modern Records: What Can We Safely Destroy?* which should be of great assistance to those who wish to answer the national call for paper and to clear valuable office space, but are desirous not to destroy documents which may be of historical value. After a brief discussion of general principles, it gives schedules of documents which it is desirable to preserve, and of those which may generally be destroyed. Copies can be had free on application to the honorary secretaries, British Records Association, c/o Public Record Office, Chancery Lane, W.C.2.

The Henry George Plimmer Fellowship is tenable at a recognized institution at home or abroad, but the Fellow will be considered to be attached to one of the Biological Departments of the Imperial College of Science and Technology, South Kensington, S.W.7, and will work under the general supervision of a professor of that department. The subject of research may include morbid anatomy, histological anatomy, chemical pathology, protozoology, bacteriology and allied subjects in either zoology, medicine, or botany. Applications for this Fellowship must be made to the Rector of the College by June 1.

The sanatorium at Nayland, near Colchester, is being taken over by the Council of Management of Preston Hall, who will provide treatment and occupational therapy and industrial training there for women suffering from tuberculosis, especially those discharged from the Services, on the same lines as at Preston Hall and at Douglas House (Bournemouth). The institution, which will be known as Nayland Hall, came under the direction of the British Legion on May 1, and is to be administered from Preston Hall by Dr. J. B. McDougall.

A national drying plant for the preparation of dried plasma has been established in Edinburgh. In spite of the call-up of men and women the number of blood donors in Scotland continues to ncrease; in Glasgow alone there are 6,000. Dumfries now has a subsidiary blood bank.

The Alnwick Rural District Council has placed on record its ppreciation of the faithful services of Dr. A. Scott Purves as its medical officer of health during the past 50 years. He was eappointed for the duration of the war.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

The Barrel Bandage

Q.—*What is the barrel bandage and how is it applied to compound fractures of the jaw?*

A.—The barrel bandage for fractures of the jaw was described in an article by Mr. W. Kelsey Fry in the *Journal* of Dec. 2, 1939 (p. 1086). Mr. Fry pointed out that the four-tail bandage was no longer used by those surgeons familiar with the treatment of fracture of the mandible. For the barrel bandage about six feet of 2-in. to 2½-in. bandage, preferably unbleached calico, is required. The middle of the bandage is placed under the jaw, well back just in front of the angle; then a simple knot is tied over the vertex of the skull (Fig. 1). Using both hands, open the knot so that the front loop comes in front of the forehead and the back portion under the occiput (Fig. 2). The two ends are then taken and upward tension is exerted, and by a slight adjustment the two running hitches are made to occupy a position slightly above and in front of the ear The two ends are then tied in a reef knot on the top of the head (Figs. 3 and 4).

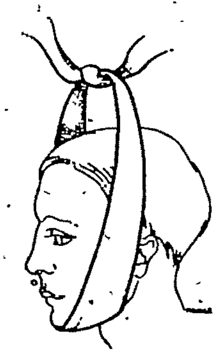

FIG. 1

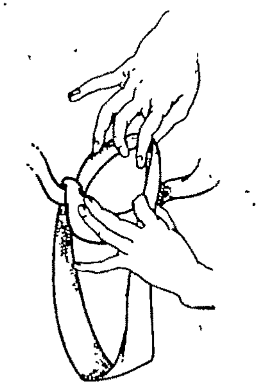

FIG. 2

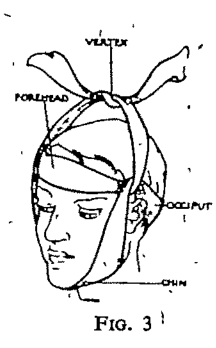

FIG. 3

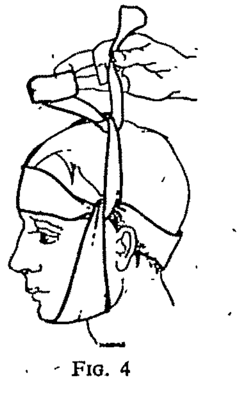

FIG. 4

Duration of Diphtheria Prophylaxis

Q.—*What is the approximate duration of the protection given by alum-precipitated toxoid injections against diphtheria, and what is the optimum period that should elapse between the two injections? Is the protection less complete when the second injection is given* *with only a two-week interval instead of four? I am often asked by parents how long the protection lasts and how I know whether it is successful.*

A.—(*a*) Such a question unfortunately cannot be answered dogmatically. "Protection" depends on the virulence of the strain of diphtheria attacking the child, and probably the dose implanted. The Ministry of Health memorandum of January, 1940,[1] stated that the immunity following artificial immunization "persists for years and perhaps for life." This is a shade too optimistic. If we measure the antitoxin in the blood of immunized children the average drops somewhat each year, and most immunologists urge a reinforcing dose of prophylactic on entry into school—i.e., from 3 to 5 years after immunization in early childhood.

(*b*) Broadly, the longer the interval between the two injections of A.P.T. the better the subsequent immunity—six months would be better than one month and four weeks better than two weeks. But we cannot risk the low immunity for six months, and a month is a reasonable compromise. Parents easily remember the date, and the system works. If T.A.F. be chosen, probably the optimum dosage would be three doses of 1 c.cm. at 4 weeks' interval.

(*c*) We could ascertain that the immunization is successful by Schick-testing every child, or a representative sample of the children. With a good A.P.T., an interval of four weeks, and a dosage of 0.2 and 0.5 c.cm. as recommended by the Ministry of Health, the conversion of Schick-positive to negative has been usually found to occur in from 90 to 100% of children—most recent figures being much nearer the 100% level.

Ring Pessaries

Q.—*In these days of rubber shortage, and from the fact that my suppliers have replied to my order for ring pessaries—"None available"—and since it is not always feasible or advisable to recommend operation for patients requiring such pessaries, is there anything else one may use in conservative treatment for such cases?*

A.—Ring pessaries are of rubber, and rubber is not to be had. Some surgical firms can no longer supply the common types of pessary. But ring pessaries may also be of the rigid type. Previously these were of vulcanite, but now the modern plastics are pressed into use, and bright, semi-transparent "rings" are making their appearance. The rigid ring pessary has always had its advocates. It is lighter, cleaner, and does not readily provoke a vaginal discharge. On the other hand it is not so easily introduced, and thus a smaller size must be used than would be possible in the case of the compressible rubber ring. If not superior, the rigid pessary is a good substitute and worthy of trial.

INCOME TAX

Purchase of Practice

W. B. asks what allowance would be permitted if he were to "buy a practice on easy terms—i.e., out of the actual income received."

*** Periodical payments of the kind indicated usually are made up of two distinct elements: (*a*) repayment of money advanced or left on loan, and (*b*) interest on the amount still outstanding. No allowance can be made as regards (*a*)—essentially such payments are "savings" of capital—but an allowance for the interest can be made if the advance is from a bank. (In the case of interest paid to private persons the borrower can recoup himself by deducting tax from the payments as they are made.)

LETTERS, NOTES, ETC.

A New Syndrome?

Dr. C. E. H. MILNER writes: I wonder if other readers have shared my recent experience in being called upon to treat cases of the type I will describe. I am at present attending four middle-aged women suffering from identical minor, but disabling, symptoms—those of what I venture to call "basket carriers' peri-articular fibrositis." All four are working, and organizing, for some 16 hours a day. All four wear complete upper and lower dentures. All four sleep indifferently and wake early, with painful paraesthesia of the right arm, which starts in the deltoid muscle and tracks, via the joint elements of the elbow, into the fingers. At breakfast they drop knives and teaspoons and are mentally irritable. As the day goes on the symptoms diminish, and by early evening they have for the most part disappeared—only to return in all their severity at bedtime, when the sufferers are only too ready, and anxious, to sleep. In all four *all* the fingers are affected, so that the question of cervical rib does not arise. On clinical examination no loss of muscular power or anaesthesia can be detected; but two of the patients present fibrositic nodules within the deltoid muscle, over the head of the humerus, as well as in the anconeus. As in so many cases of fibrositis, the cause appears problematical—possibly toxic, possibly postural, possibly occupational. Treatment has been disappointing. Salicylates have been prescribed, together with tincture of gelsemium; and alternately small doses of Lugol's solution. The total fluid intake has been doubled or trebled. Coffee has been forbidden; likewise sherry—as if there were any need! Local heat and local deep, vigorous massage have afforded but temporary relief. The simplest prescription has perhaps produced the greatest comfort—a good hot morning bath, with a handful of washing soda; and a couple of tab. codein. co. at bedtime.

Nit-wits

Dr. DEVEREUX FORREST (Torquay) writes: I am quite at a loss to find the point of the frequent papers recently on the greater incidence of infestation among those of meaner intelligence. Surely this is what a person with an average percentile intelligence score might reasonably expect—to wit, that it is highly probable that the least intelligent will also be the least careful in their personal hygiene and habits, thus being more prone to get infested; that when they are infested they will be slower to find it out; and that when they do find it out they will be slower still to deal with it adequately. I trust that this letter has not suggested a probable poor percentile intelligence score by myself!

Factors Influencing Lactation

Dr. JEAN MACKINTOSH (Aberdeen) writes: I should like to correct an error which has crept into your account of the meeting of the Scottish Group of the Nutrition Society (April 24, p. 517). There it states that "Dr. Mackintosh excluded diet as one of the main causes" of decreased incidence of breast-feeding. The relevant sentence in the paper reads as follows: "There are several other factors, however, which come into play besides any nutritional deficiency in the successful establishment and maintenance of breast-feeding." Good nutrition is very important, but there are other psychological factors which also play an important part. The incidence of breast-feeding at six months in the recent surveys quoted in my paper ranged between 30 and 40%.

Legal Protection for Serving Medical Officers

To judge from inquiries received from time to time some doctors holding commissions are still under the impression that because they are employed in the armed Forces it is not necessary for them to belong to one of the defence societies, on the assumption that such employment makes them immune to legal attack. As pointed out in these columns three years ago in a letter on the subject from the presidents of the Medical Defence Union and the London and Counties Medical Protection Society, legal proceedings against a medical man may be taken months, if not years, after the alleged negligence or misdemeanour has occurred. Every doctor is liable to legal attack, and he may require protection even against the authority by whom he is employed. Equally important is the fact that the Government does not accept responsibility for alleged errors of medical officers; it has never undertaken to do so, though in exceptional cases it has been known to take this action after pressure from a defence society. Again, a number of cases have occurred in which defence societies have defended doctors brought before courts martial on charges of alleged negligence or of alleged disciplinary offences. Added to all this members of a defence society may obtain free advice on a number of difficult questions; and, finally, it is worth while remembering that the subscription is exempt from income tax.

The Epiglottis in Anaesthetic Deaths

Dr. ERNEST CULPIN (Brisbane) writes: The annotation on the epiglottis in anaesthetic deaths (Sept. 12, 1942, p. 344) is highly important, but the fact that such an article should have so prominent a position is a sad commentary on the medical profession. A freely patent airway is an essential for all anaesthetics, and if the profession would learn from a natural demonstration such an article would not be necessary. It must be assumed that all members of the profession are acquainted with the gross anatomy of the ai passages. The simple lesson is given by the position of the head mouth, tongue, jaws, and neck of the athlete when nearing the tap in a 440-yards race or a 100-yards sprint, at which time he i endeavouring to get all the air (oxygen) he can by providing th clearest possible airway. This should be the position of the patie under anaesthesia, particularly during operation for removal tonsils, when the epiglottis and probably the larynx will be und direct vision of the surgeon during the whole of the operation; addition the entry of blood or dirty tonsillar secretion into the lary will be controllable and prevented. The epiglottis will have opportunity of occluding the larynx. The reported cases, wherei is stated that after digital freeing of the epiglottis conditions w satisfactory, in themselves prove that the epiglottis should not would not have caused the trouble had not neglect allowed i do so.

LONDON SATURDAY MAY 15 1943

HEAD INJURIES IN MOTOR-CYCLISTS

WITH SPECIAL REFERENCE TO CRASH HELMETS

BY

HUGH CAIRNS, D.M., F.R.C.S.

AND

H. HOLBOURN, D.Phil.

(From a Military Hospital for Head Injuries and the Nuffield Department of Surgery, Oxford)

In an earlier paper (Cairns, 1941) attention was called to the use of crash helmets to alleviate the head injuries of motor-cyclists, and 7 cases were reported. We now have records of 106 accidents in which we have been able to examine the crash helmet and, usually, the patient. This material provides further information about head injuries in motor-cyclists, and also enables us to compare the relative values of different types of helmet.

Two main varieties of helmet are in use. In one the outer shell is composed mainly of hard vulcanized rubber; in the other, of compressed wood pulp. Apart from their composition, there are important differences of construction. In the vulcanized type (Fig. 1) the inner suspension system is connected to the outer shell by means of a stout cord at the base of the helmet; if the cord is broken there is nothing to prevent the rider's head from coming into contact with the crown of the outer shell. In the pulp type (Fig. 2) the inner slings are stitched separately into the substance of the outer shell, and the stout cord at the base merely retains the hatband in place.

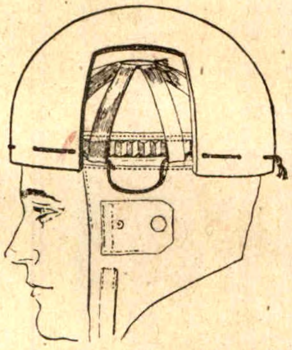

FIG. 1.—Vulcanized rubber helmet.

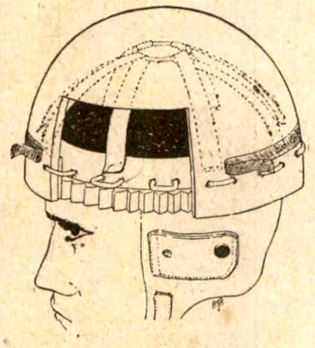

FIG. 2.—Pulp helmet.

Material

Our material consists of cases admitted to a Military Hospital for Head Injuries and extramural cases brought to our notice from various sources because of our interest in crash helmets (Table I). Of the hospital cases, those admitted after the acute stage were sent for assessment of their fitness to return to duty, for convalescence, or for special treatment; they were thus a specially selected group. The cases admitted in the acute stage were unselected, except that they did not include the accidents in which the motor-cyclist died before he could be moved to hospital, nor the mild accidents in which the motor-cyclist did not require hospital treatment. The immediately fatal cases and a few of the mild ones are represented in the extramural group—the fatal cases to a disproportionate extent. These have been largely traced through the help of ordnance depots receiving damaged helmets.

TABLE I.—*Head Injuries in Motor-cyclists With and Without a Crash Helmet (Figures for Non-crash-helmet Cases in Black Type)*

	Hospital Cases				Extra-mural Cases	Totals
	Admitted in Acute Stage		Admitted in Subacute or Chronic Stage			
Very mild (no amnesia)	1	**(3)**	3	**(10)**	9	13*
Mild (amnesia < 1 hour)	6	**(6)**	14	**(21)**	7	27*
Moderately severe (amnesia 1–24 hours) ..	8	**(10)**	23	**(53)**	4	35
Severe (amnesia 1–7 days)	4	**(2)**	7	**(52)**	1	12
Very severe (amnesia > 7 days)	2	**(9)**	3	**(35)**	1	6
Unclassified (duration of amnesia unknown) ..	—	—	—	**(4)**	3	3
Fatal	1	**(3)**	—	—	9	10
Totals	22	**(33)**	50	**(175)**	34†	106

* Six of the cases in these two groups were so slightly injured as not to require hospital treatment.

† In 2 cases a patient had two separate accidents while wearing the same helmet.

In classifying the cases according to their severity we have used the total duration of amnesia. With certain limitations common to all the subgroups, this provides a rough measure of the intensity of concussion. The severity of head injuries depends on other effects besides concussion—effects such as bruising, infarction, or laceration of parts of the brain, and intracranial haemorrhage or infection—but the clinical state of concussion, as judged by the duration of amnesia, is the only available measure.

In the first six case reports which follow we have attempted to give a fair sample of our material. Cases have been selected from the groups in Table I, so far as possible in proportion to the number of cases in each group. However, we have not taken a case from the "severe" group, since its cases closely resemble those of the "moderately severe" group.

A Very Mild Case

Case 1.—While travelling at high speed Cpl. A., aged 22, hit a rut in the road and was thrown on to his head. The left frontal region of his crash helmet (vulcanized type) showed a large area of abrasion and a fracture, and his triplex goggles were broken into many fragments, but these did not become detached (Fig. 3). He had a cut in his left eyebrow, and his forehead was bruised. He felt dazed for some hours, but did not lose consciousness. He complained of headaches for four days, but remained with his unit. Six months later he was performing full duty efficiently. (Case of Surg. Lieut. B. Robinson, R.N.V.R.)

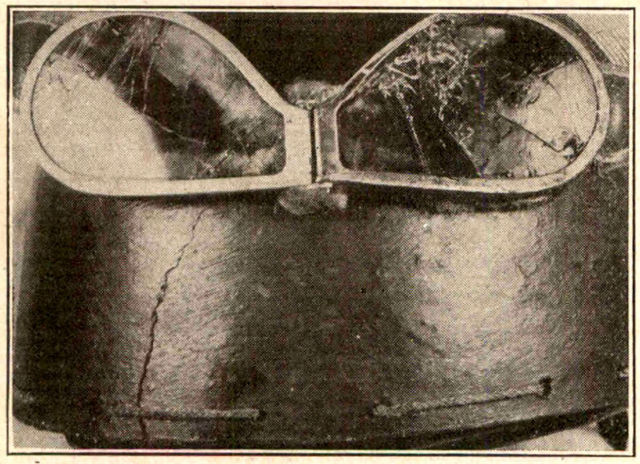

FIG. 3.—Case 1. Broken crash helmet, seen from the left, and goggles, which were worn upside down. The wearer was able to remain with his unit.

A Mild Case

Case 2.—Rifleman B., aged 19, was admitted to hospital after the second of two accidents at an interval of five days. In the first he had had a tyre burst while travelling at 30 to 35 m.p.h., and had gone into a ditch and pitched over the handle-bars. He woke up two minutes later and found himself sitting in the ditch. He was taken back to his unit in a lorry. Five days later, on his next cycle journey, he collided with a lorry which suddenly turned right when he was overtaking it on a main road at 35 m.p.h. This time he was amnesic for 10 minutes, and had bruises on the left side of his forehead, left shoulder, and both knees. Radiographs showed no fractures. After 23 days in hospital he returned to his unit. Although of normal intelligence, he was irresponsible to a degree that probably rendered him unusually prone to accidents.

His crash helmet (pulp type) showed high up in the right frontal region areas covered with a thin layer of earth that were probably produced by the first accident. Lower down in the right frontal region was an extensive area of deeper abrasions and lacerations that was probably caused by the second accident.

Moderately Severe Cases

Case 3.—Cpl. C., aged 24, also had two accidents. In the first, which belonged to the very mild category, he ran into a car that was on the wrong side of the road. His right external malleolus was struck by the bumper, and his handle-bar caught the front-door handle of the car. He was flung off on to the back of his head, but did not lose consciousness. He was unable to stand on his right leg for a quarter of an hour after the accident, but remained at duty and was riding a motor-cycle again next day. His pulp helmet showed a fracture in the occipital region (Fig. 4), which was identified by the patient and his commanding officer as being the result of this accident.

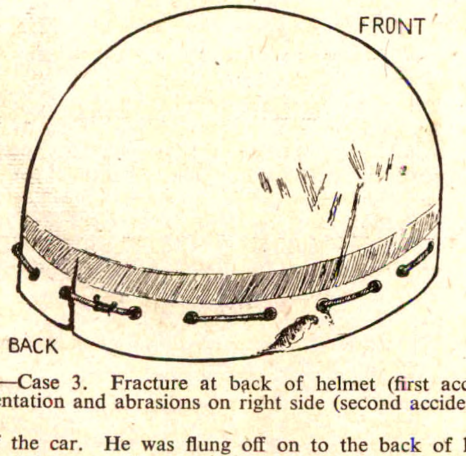

FIG. 4.—Case 3. Fracture at back of helmet (first accident). Indentation and abrasions on right side (second accident).

One month later he ran into a flock of sheep. This time his head injury was moderately severe: he was amnesic for two hours and had bleeding from the right ear, with a fracture of the right squamous temporal bone running into the petrous bone. His crash helmet (the same one) showed abrasions on the right side, with a dent at the edge (Fig. 4). He also had bruises of the right shoulder and elbow. He was kept in bed for 17 days, and then, after being up for only half a day, was transferred to a convalescent hospital, where he at once began to have headache and dizziness on exertion and soon became depressed. He was therefore eventually admitted to this hospital. Examination showed no signs other than the fracture of the skull. He was reassured, given graduated exercise, and returned to duty 12 weeks after the second accident.

These cases illustrate the value of crash helmets, and they also raise certain other aspects of accident prevention which, though beyond the scope of this paper, nevertheless deserve more attention than they have received in the past. In Cases 2 and 3 the successive accidents within a short period suggest that these patients might have been more prone to accidents than normal, and that after one accident the liability to accidents is for a time increased.

In Case 3 the treatment given after the second accident was not satisfactory. There is still a tendency to keep patients in bed too long after a mild head injury and then to discharge them from hospital without adequate reassurance or any attempt at physical hardening. In these circumstances unwonted exertion is often followed by headache and dizziness, and the patient, now beyond the control of a medical officer and perhaps at the mercy of over-sympathetic relations, loses confidence in his recovery. His fears aggravate his symptoms and may render him unfit for duty.

Case 4.—Signalman D., aged 28, had a head injury on Nov. 27, 1941. According to another dispatch rider, who was following him, they were travelling at 40 to 45 m.p.h. along an arterial road, when a car in front of them suddenly pulled out, and the patient had to brake so hard that he skidded and fell, striking his head against the kerb. His crash helmet (pulp type, Fig. 5) was penetrated in the right frontal region; the surrounding area showed lines of fracture and numerous abrasions, deepest at the anterior edge of the helmet. He had a retrograde amnesia of 3 to 4 minutes and a post-traumatic amnesia of just under 24 hours. Radiographs of the skull showed multiple fissured fractures of the right fronto-parietal region extending on to the greater wing of the sphenoid (Fig. 6), but without any depression. The right fronto-malar suture was also separated. When he was examined two months later no abnormality of the central nervous system could be detected. He did well, and returned to his unit 10 weeks after the accident.

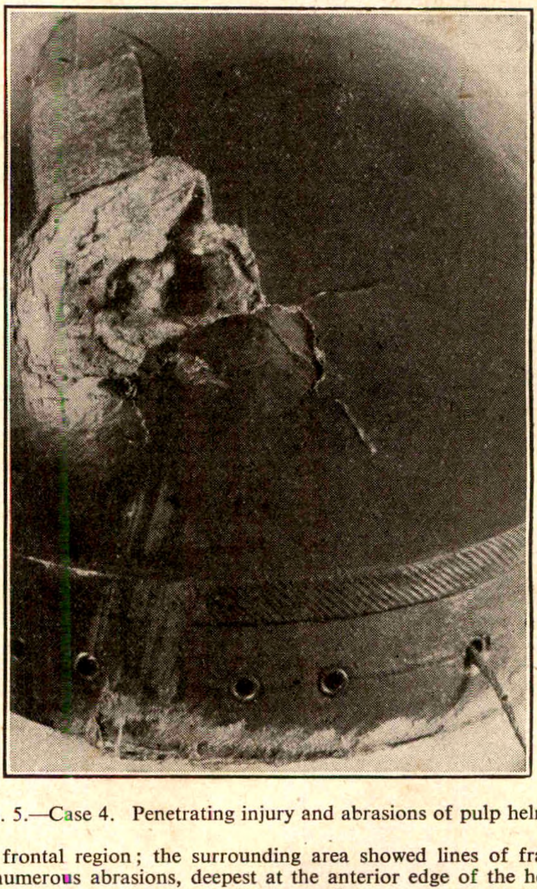

FIG. 5.—Case 4. Penetrating injury and abrasions of pulp helmet.

In this case the blow must have been particularly severe, for helmets of this type rarely show gross fractures, and as a rule the skull beneath them is not fractured. It is likely that without the protection of a helmet this man would have had a compound depressed fracture of the skull, with penetration of the dura and severe, perhaps fatal, laceration of the brain.

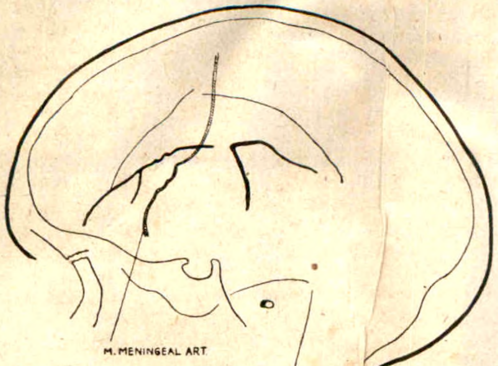

FIG. 6.—Case 4. Multiple fissured fragments of skull in right fronto-parietal region without depression.

A Very Severe Case

Case 5.—L'cpl. E., aged 24, ran into the back of an unlit stationary lorry in the middle of the night. He had a small scalp wound above the left ear, with a Y-shaped fracture of the underlying squamous temporal bone, and a superficial graze on the left cheek; he also bled from the right ear. His retrograde amnesia (estimated four months later) was 8 days and his post-traumatic amnesia about 20 days. On admission to hospital he was in coma, with spastic limbs, bilateral ankle clonus, and extensor plantar responses on each side. Within 12 hours he became violently restless, and remained in this state for 8 days; but after hot baths he became quieter. He was, however, still confused for some days, and during this time he had an incomplete and temporary right facial palsy of the peripheral type. The signs of organic neurological damage cleared up completely, but he still complained of headaches on exertion and gross impairment of memory. Attempts at active physical and psychotherapeutic rehabilitation failed, and he was invalided from the Army 4½ months after the accident.

His crash helmet (pulp type) showed a fracture with slight depression at the left lateral edge. Beneath this fracture the rim of the fibre hatband was broken, and the break corresponded with the scalp wound above the left ear.

This patient had a severe brain injury, with fracture of the base of the skull, which might have been fatal if he had not been to a considerable extent protected by the crash helmet from the full violence of the blow. Eventually he made a good recovery; but after such a prolonged period of post-traumatic coma and amnesia the capacity for satisfactory work may be slow to return, and in this case recovery was complicated by the fact that before the accident his adjustment to Army life had not been altogether satisfactory.

Fatal Cases

Case 6.—L'cpl. F., aged 27, came over the crest of a hill to find an oncoming car turning right towards the entrance of a station. His cycle struck the offside front wheel of the car, and he was thrown a distance of 40 feet, striking his head against cobbles (Fig. 7). His crash helmet (vulcanized type) had an extensive fracture on the left side (Fig. 8), and there was an extensive fracture also in the left temporo-parietal region of the skull, spreading into the middle fossa. The patient never recovered consciousness, and died 51 hours after the accident. Before death he had right hemiparesis and rapid bubbly breathing. Necropsy showed, in addition to the skull fracture, extensive laceration and haemorrhage of the left hemisphere beneath the site of the blow, together with a small amount of extradural clot. (From notes supplied by Brig. Hedley Whyte, D.S.O.)

FIG. 7.—Case 6. Diagram of accident.

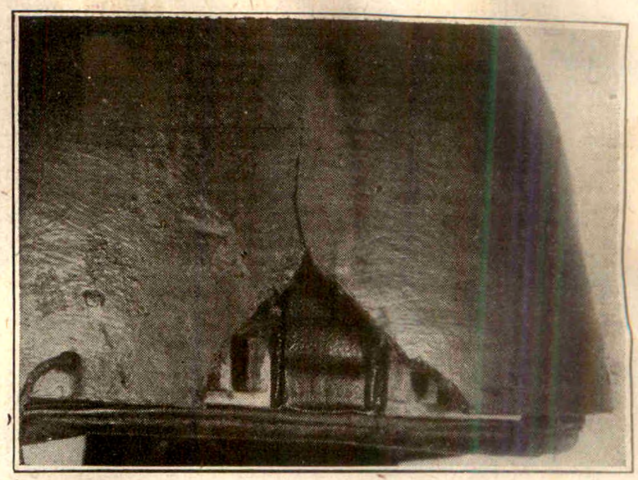

FIG. 8.—Case 6. Fracture of vulcanized helmet.

In this case a less brittle and more strongly buffered helmet, protecting a wider area of the temporal region, might have prevented the fatal brain damage. Violent blows in the unprotected region of the external ear and mastoid process seem to be very liable to produce death.

In the fatal cases which we have examined death was not always due to head injury. In the following case—the only fatal case among those admitted to our hospital—the crash helmet was effective in preventing brain damage, but the patient died from bronchopneumonia secondary to injury of the thorax.

Case 7.—Travelling fast in daylight, with his head bent forward, Pte. G., aged 29, crashed into the back of a stationary lorry. Witnesses say he bounced back about six feet and landed sitting on his motor-cycle, then slowly keeled over sideways. A few hours later he was admitted to hospital in a comatose restless condition and showing signs of traumatic asphyxia. Temperature 103°; pulse rate 150; respiration rate 40. His crash helmet (pulp type, Fig. 9) showed a large dent high up in the frontal region, with an eccentric deep semicircular mark which suggested that he had run into a piece of piping projecting from the back of the lorry, though it is stated that he hit the tailboard. There was also a deep transverse groove running across the posterior surface of the helmet. No signs of a lesion could be found in the scalp or skull. He had a bruise on the front of his sternum, fractures of upper thoracic vertebrae, and compound fractures of the left second and fourth metacarpals. Lumbar puncture (10 hours after injury) showed lightly blood-stained fluid under an initial pressure of 140 mm. H_2O, with a protein content of 100 mg. per 100 c.cm. and 7,200 red cells per c.mm. During the next three days he became less deeply unconscious; but his breathing

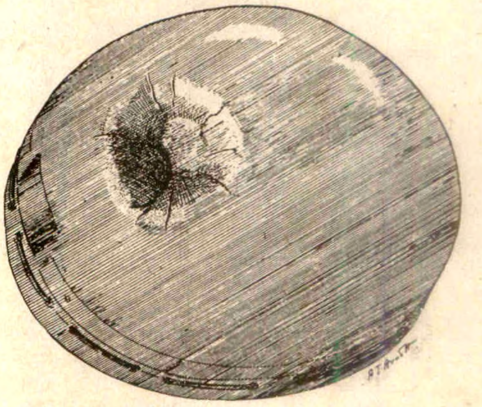

FIG. 9.—Case 7. Severe indentation of pulp helmet.

remained rapid and stridorous, and he gradually developed signs of bilateral bronchopneumonia, with a small pneumothorax on the right side, widening of the upper mediastinal shadow, disappearance of the heart sounds, and a persistently rapid pulse with gallop rhythm. He died four days after the accident.

Necropsy (carried out by Drs. Robb-Smith and Dorothy Russell) showed a fracture of the sternum beneath the bruise on the chest wall. There were considerable extravasation of blood in the upper mediastinum, slight bruising of the wall of the left ventricle of the heart, and bronchopneumonia. Neither the scalp nor the skull showed any sign of damage, and the only lesion found on the surface of the brain was a small amount of subpial haemorrhage along the medial sagittal border of each cerebral hemisphere. Coronal sections showed numerous petechial haemorrhages, with softening of the white matter, symmetrically scattered through both temporal lobes, linear haemorrhages in both fusiform gyri, and a few perivascular haemorrhages in the left frontal lobe. These were not sufficient to cause death, and on microscopical examination there were no signs of fat embolism. There was some bruising of the dura just above the foramen magnum and of the muscles of the neck. The spinal column showed a fracture-dislocation between the third and fourth thoracic vertebrae and a crush fracture of the body of the sixth thoracic vertebra, without injury to the spinal cord.

In this case there was undoubtedly a very severe blow to the head, and the crash helmet appears to have been most effective in preventing damage to the brain and skull; but it was not able to absorb all the energy of the blow on the head, and some of the force was transmitted to the spinal column. The primary cause of death was bronchopneumonia and mediastinal haemorrhage, due to a second blow on the chest and possibly also to the spinal injury.

Marks on the Helmet

From the marks on the outer shells of the helmets it is possible to deduce the positions of the blows and to some extent their severity. On the vulcanized type of helmet a serious blow generally causes a triradiate Y-shaped fracture of the outer shell, with its junction near the centre of the blow and the vertical limb usually extending to the edge of the helmet. With blows of still greater severity the upper arms of the Y may curve round and reach the edge, so that portions of the helmet become detached (Fig. 10).

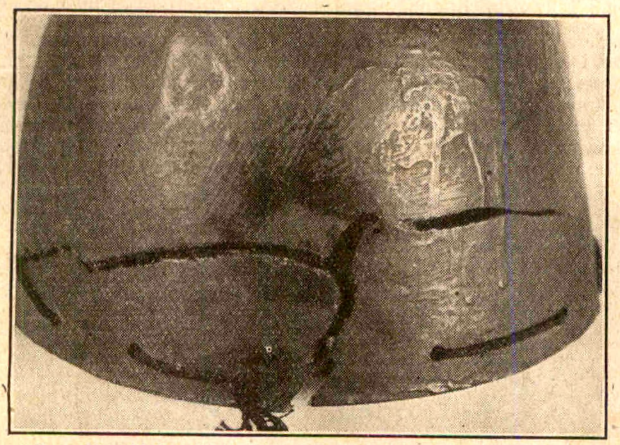

FIG. 10.—Vulcanized rubber helmet showing typical severe blow in the occipital region. The wearer was able to continue at duty.

The imprint of the object causing the blow is generally found near the junction of the Y. If the blow is due to the road inconspicuous groups of small pits, the imprints of the sharp corners of the road metal, are found at this point. The pits often have small tails to them, due to a small amount of "slip" between road and helmet. The pits may be easily overlooked, as they appear insignificant in comparison with the long and deep abrasions produced when the helmet is sliding along the surface of the road. And it must often happen that the pits due to the original blow are completely obliterated by abrasion marks due to subsequent sliding. In less serious blows the inconspicuous pits may occur without any fracture.

A blow by another vehicle usually causes a fracture. Near the centre of the fracture lines the paint may show an extremely faint polish at the summits of its irregularities, akin to the polish which occurs on the thicker parts of a starched collar from the pressure of the iron (Fig. 10). Sometimes the impact of another vehicle produces a smooth area denuded of paint.

The pulp type of helmet, being less brittle, seldom shows gross fractures; instead, an indented slightly softened area is produced by the blow. In this area there is slight wrinkling of the material, with little tendency for the wrinkles to run to the free edge (Fig. 9). Impact with the road usually causes small jagged tears of the layer of gossamer covering the helmet. The only clear evidence of impact with another vehicle is obtained in cases such as Case 7, in which an imprint of some geometric shape is seen in the helmet. No imprints of geometric shapes are found in the vulcanized helmets, presumably because the material breaks before it is sufficiently deformed to leave a permanent impression.

Multiple Blows

In 40% of 81 cases the helmet showed marks of more than one blow. In 2 cases the history and the character of the indentation in the helmet suggested that the patient struck two objects at once, one in the front part of the crown of the helmet and the other in the occipital region. In another case the helmet was crushed by the wheel of a lorry and fractured on both sides. In the remaining cases it is likely that the patients received successive blows against widely different areas of the helmet. There were indications in the marks that one blow was more severe than the others.

Case 8.—Pte. H., aged 27, struck the back of a lorry in daylight while riding his motor-cycle. He had a scalp wound in the forehead, a fractured frontal sinus, amnesia for two days, and double vision for two to three weeks. His crash helmet (vulcanized type) showed an irregular defect in the mid-frontal region, and, at the apex of this defect, depression of one fragment of the shell. In the right postero-lateral region the shell showed a second fracture, which was surrounded by areas of abrasion.

In this case there were clearly two blows—one on the front and one on the back of the helmet. Possibly the first blow was caused by the patient's head striking the lorry, and the second by his subsequent fall to the ground. That the main blow was on the forehead is shown by the severity of the damage to the front part of the helmet and by the fact that the damage to scalp and skull was beneath that area.

Evidence for multiple blows is also obtained from those cases in which there are fracture of the jaws and damage to the skull in some part other than the frontal and temporal regions.

Case 9.—Lieut. I., aged 24, crashed into a lorry which suddenly turned right into a side road. On admission to hospital two hours later he showed a simple fracture of the lower end of the left fibula, a comminuted fracture of the symphysis of the mandible, a fracture of the left condylar process of the mandible, and a fracture of the adjacent tympanic plate. There was no other fracture of the skull. His crash helmet was unmarked in the front, but showed a line of abrasions and a fracture in the left occipital region, with some general depression of the left occipital part of the helmet. The patient was amnesic for 7 days, and during the first part of this period was in a very confused state. He subsequently made a good recovery.

In this case there were obviously two blows—one on the face and one in the occipital region. Most of these cases of multiple blows appear to have occurred when the rider collided with a vehicle, such as a lorry or a taxi, and the first blow was probably due to striking the vehicle, the second to striking the ground. But in one fatal case of which we have read the report there is a circumstantial account that the rider fell and struck a fallen tree-trunk, then bounced up into the air, fell, and struck his head again.

Our observations confirm the experience of Rowbotham (1941) that "in road accidents in particular the head may be struck more than once." In the initial examination of a case of head injury, therefore, the medical officer should not be satisfied with finding one scalp wound, but should search the head for evidence of another. In a case which came to our notice neglect of this rule resulted in death from meningeal infection through an untreated wound of the hairy part of the scalp.

The Site of the Blow

The site of the marks on the helmet and the damage to the underlying scalp or skull showed a close correspondence. In 30% of our cases we could not establish a precise relationship —usually because there was no mark on the scalp or skull (e.g., Case 7), but sometimes because the marks on the head, though close to the marks on the helmet, were not directly below them. In only 5% was there a definite variance between the site of the marks on the helmet and those on the head. In the remainder—i.e., in 93% of those in which requisite data were available—correspondence was precise.

The helmet thus provides a permanent record of the blow, and this is useful in patients who come under observation after their bruises and lacerations have healed. In some of our cases it has led to detection of fractures of the skull which had been overlooked at the first radiographic examination.

When the site of the main blow is plotted diagrammatically it is seen that blows on the frontal quadrant are almost as frequent as all the others put together (Fig. 11 and Table II).

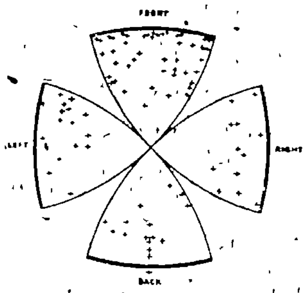

FIG. 11.—Diagram of site of main blow in 91 cases.

Blows on the front half of the helmet are over twice as frequent as blows on the back half. The majority are at or fairly near the edge of the helmet (the average height of blows is 4.5 cm. above the brim), and blows on the crown, an area approximately equal to that of a quadrant, are very rare: there were only 3 cases in which the blow was primarily on the crown. The case of the motor-cyclist is quite different from that of the equestrian, who starts his fall from a considerable height and has time enough to perform the rotation necessary for a fall on to the crown of his head. The motor-cyclist rides close to the ground, and in an accident usually falls from his machine in a forward, or lateral and forward, direction without enough height to perform the necessary rotation.

TABLE II.—*Effects of the Main Blow on Skull and Brain in Relation to Site of Injury*[*]

Site of Injury	Total No. of Cases	Cases with Skull Fracture	Deaths attributable to Brain Injury
Frontal ..	47	16	3
Lateral ..	28	17	3
Occipital ..	21	3	—

These observations show the importance in design of providing particularly good protection at and immediately above the edge of the helmet, especially at the front, where blows are two to three times as common as in any other part.

Effects of Blows in Different Regions

The outstanding feature of Table II is the mildness of the effects of blows in the occipital region in comparison with those on the frontal and lateral regions. It may be that in motor-cyclists a blow in the occipital region occurs only after the body of the motor-cyclist has almost come to rest; and that this is the explanation of the slightness of occipital injuries. Motor-cyclists probably do not turn somersaults in mid-air unless the initial violence is taken on some other part of the body before they turn over on to the occiput. Furthermore, the occipital region is more completely protected by the helmet, and below that by the neck muscles, than are other parts of the cranium.

Blows on the frontal and lateral regions are much more dangerous, and the figures of deaths and of fractures suggest that the lateral blow is the more dangerous of the two. The lateral regions are not well covered by the present designs of helmet, and the main effect of the blow may fall on the cranium below the level of the helmet. Similarly, the lower part of the frontal region is exposed to blows, particularly when motor-cyclists wear a helmet which is on the small side: in them the main violence may be applied to the unshielded supra-orbital ridge.

Of the 3 cases in which the blow was on the crown of the helmet, one was the result of a mild glancing blow that produced only momentary amnesia. In the other two the blow was severe, and was associated with a crush fracture of the spine. One of these has been already described (Case 7); the other is as follows:

Case 10.—Driver J., aged 20, was following a van at 40 m.p.h. when it suddenly slowed and swung into the middle of the road in preparation for turning left. His cycle struck the near-side mudguard of the now almost stationary van, and he was flung over the handle-bars. He was rendered momentarily unconscious, and had an abrasion on the bridge of his nose, pain in the back, and fractures of metacarpal bones of both hands. No signs developed in the central nervous system, but radiographs showed a crush fracture of the seventh thoracic vertebra. He returned to duty four months after the accident. (Major P. Clarkson's case.) His crash helmet (pulp type) showed numerous pitted and linear abrasions on the crown in an area 20 by 9 cm., extending forwards to the upper part of the frontal region. The patient's story was that his head had struck the back of the van; but this is unlikely, for in one of the abrasions was a fragment which was identified as road metal. In the inner sling of the helmet the stitches holding the two anterior loops to the outer shell were completely torn through.

It is significant that this case and Case 7 are the only two cases in the series in which a fracture of the vertebral column was found. However, the incidence of spinal column and spinal cord injury in motor-cycle accidents cannot be properly assessed without including a study of those patients who die soon after the accident and before they reach hospital; and in these cases thorough post-mortem examination is rarely made. In a series of 46 fatal motor-cycle accidents studied from the records of the Claims Section of one of the Army Commands there were three cases of instantaneous death ascribed, without necropsy, to broken neck. While the evidence is thus not very satisfactory, it does suggest that spinal injury is relatively uncommon after motor-cycle accidents, but that it should be looked for especially in those cases in which the blow is on the top of the head.

Absence of Marks on the Helmet

The value of head protection has been criticized on the grounds that brain damage is produced by violence applied to parts other than the head and transmitted to the base of the skull through the facial bones or the spinal column. In our series there were only 9 cases in which the helmet shell did not bear any marks of a blow, though the patient was regarded as a case of head injury.

Of these cases 5 proved to have had a head injury. In three of them there was laceration of one eyebrow below the crash helmet, which was too small for its wearer. In one case there was evidence of a blow on the leather flap covering the left ear. In the other case the lining of the helmet was broken and it is presumed that there was a blow on the head: this was one of our early cases, seen at a time when we were not yet expert at recognizing marks on the shell.

In 1 case the nasal bones were fractured and the patient did not become unconscious. In 2 cases the patient had a fracture of a limb bone, amnesia of short duration, and no evidence of a blow on the head or face. In these two cases it is possible that there was no brain injury, for amnesia may occur in uncomplicated cases of fracture of the femur in which there is no head injury. In one such case it was possible to demonstrate that, although the patient appeared to respond rationally during the stage of primary shock, he subsequently had amnesia for the greater part of the period. Another possible explanation for these cases is that there may have been a blow in the region of the foramen magnum transmitted through the vertebral column; but in the absence of any evidence of vertebral injury this seems unlikely.

In the ninth case, described as one of concussion, closer inquiry, after we had failed to find any marks of injury to the helmet, revealed that the man had not been concussed but had become amnesic from fright.

Case 11.—Gunner K., aged 27, was admitted to our hospital some two months after a motor-cycle accident suffering from the after-effects of head injury. The story obtained by the medical officer was that the man had collided with a car and that his retrograde amnesia was 1 to 2 seconds and his post-traumatic amnesia 6 hours. His complaints were of fairly continuous headaches, dizziness, and a feeling of weakness on attempting to do physical training. Examination showed no signs in the central nervous system. As his crash helmet bore no marks and he was obviously a rather nervous individual, his history was gone into more closely. Inquiry disclosed that there was in fact no retrograde amnesia and that his post-traumatic amnesia had not begun until half an hour after the injury, and had lasted until he was awakened 5½ hours later by a medical officer, who told him that he had had an accident. With the patient under pentothal, Capt. P. W. Nathan was later able to obtain a connected story of the whole period of amnesia and also fresh information about the man's anxieties and fears, which provided an adequate explanation of his symptoms.

---

[*] The number of cases was not large enough to enable us to estimate the relationship of the site of the blow to the duration of amnesia.

It is probable that this case would have remained under a false label if absence of marks on the crash helmet had not led to closer inquiry.

Thus in the 106 accidents we are considering there is evidence of a blow on the head in all but 4. Of these four, one was a case of broken nose and another was a case of amnesia from fright. In the remaining two it is possible that slight brain injury may have resulted from violence applied to the base of the skull through the spinal column, though it is more likely that the brief amnesia which occurred was due to shock associated with fracture of a long bone. These observations do not disprove the contention that brain injury may result from injury to the face or spinal column, but they do establish the fact that in motor-cyclists brain injury is almost invariably associated with a blow on the head, protection against which can be provided by a properly fitting crash helmet.

Damage to the Helmet Lining

In considering the information which can be obtained from knowledge of the site of the blow we have dwelt of necessity on the damage to the outer shell, but it is important to recognize that the protective value of a helmet should rest to a great extent on its inner lining. With blows on the crown of the helmet the slings should absorb the energy of the blows, but they cease to do this as soon as the rider's head comes into contact with the outer shell. Owing to the rarity of blows on the crown, these slings are rarely brought into play; for in pulp helmets, in which it is to some extent possible to judge the strain placed upon them, the slings were broken in only two cases.

Against frontal, lateral, and occipital blows the hatband offers protection in proportion to its power to act as a buffer. This part of the inner lining could be altered with advantage, especially in the frontal region, where blows are most common.

The presence of a cord on the outer surface of the shell has been criticized by Gardner (1941) on the grounds that friction of the cords increases the deceleration of the head, thus rendering the effects of the blow more severe. We agree that the severity of the injury depends largely on the rate of deceleration, and that this rate can be reduced by sliding. Gardner suggested that the presence of the cord increased materially the risk of spinal injury. In our series of 104 cases there were only 2 cases of fractured spine, in one of which the blow was on the crown of the helmet and the cord was intact. We consider that the cord has proved to be an unnecessary feature of the design, and are thus in general agreement with Gardner. But we do not think that it is important in promoting deceleration, because the coefficient of friction between the surface of the helmet and the road, or whatever object the helmet strikes, is not altered adversely by the presence of the cord.

Our main objection to the cord concerns its use in the older type of vulcanized helmets as the connecting link between the inner lining and the shell (Fig. 1). In our series the outer cord was broken in 30 of the 52 vulcanized helmets and in only 9 of the 52 pulp helmets. This difference is significant, and is due to the fact that in the vulcanized type the cord is stretched when the helmet is struck and forced further on to the head; whereas in the pulp type the cord is not stretched as a result of the blow, since each sling, being stitched to the shell separately, is independent of the cord. As the helmet moves along the surface struck, the friction is usually enough to break the stretched cord of the vulcanized helmet, but does not suffice as a rule to break the unstretched cord of the pulp helmet. These effects may be compared with the well-known observation that when string is tightly stretched it can be much more easily cut with a pocket-knife than when it is not under tension.

The Theory of the Mode of Action of Crash Helmets

The chief functions of a crash helmet are two: (1) prevention of local injury in the region of the blow; and (2) prevention of effects remote from the region of the blow—viz., concussion, so-called contrecoup injury, etc.

Prevention of Local Injury.—The shell of the helmet acts partly by spreading the blow over a wider area, thereby diminishing its intensity at any one point. It is in this way, for example, that the helmet protects the scalp and skull from the pointed parts of the object struck, such as the sharp fragments of road metal projecting from the surface of the road. Hence, even by the action of the shell alone, some diminution in the number of fractures of the skull should be expected. In addition, some of the fractures should be prevented from becoming depressed, thereby reducing the liability to dural penetration and damage to the underlying brain. Since, owing to the stiffness of the shell, bending of the skull by the force of the blow is also lessened, there should be less contusion of the brain at the site of impact. The so-called "coup" lesion is, in our view, due to the bending of the skull under the blow.

The shell of the helmet also functions by "lengthening the blow"—that is, by spreading it out over a longer interval of time, so that it is not so intense at any particular instant. However produced, lengthening reduces not only the local injury but all other effects of the blow. The shell accomplishes this by sliding over objects for some time instead of stopping more abruptly, as the unprotected head would do owing to its greater coefficient of friction. But the main way in which the blow is spread over a longer time is by means of the buffering action of the slings and hatband. The blow lasts during all the time that the slings are being stretched or the hatband is being compressed, instead of only during the time taken to deform the scalp and skull. It is consequently reduced in intensity, and the local damage to scalp, skull, and brain is less severe. These parts of the existing types of helmet could be improved.

The blow is also lengthened to some extent by the rotation of the helmet relative to the head.

Prevention of the Remote Effects of the Blow.—The blow produces a change in the velocity of the head which may be either an acceleration or a retardation (Denny-Brown and Ritchie Russell, 1941). Calculation shows, however, that the change in the linear (or straight-line) velocity of the head produces only insignificant effects. The main effects are produced by a change in rotational velocity. As a rule the blow imparts a sudden rotation to the head. This is the cause of all gross bruises or lacerations of the cortex remote from the site of the blow. All the available evidence points to its being also the cause of the concussion. Anything which reduces the force of the blow will tend, other things being equal, to diminish the sudden rotation and its attendant lesions. Spreading the blow over a larger area is not effective from this point of view, since the total force is unaltered. But spreading it over a longer interval of time is to some extent effective, since the total force at any instant is reduced. Hence, owing to the sliding action of the shell and the buffering action of the slings and hatband, the helmet is effective in reducing the so-called contrecoup injuries and concussion.

Observations on the Effects of Crash Helmets

There are three groups of motor-cyclists to be considered: (1) those who die on the road before they can be moved to hospital—approximately 20% of 46 fatalities in one Army Command whose records we examined; (2) those who are

TABLE III.—*Influence of the Crash Helmet on the Incidence of Fracture of Skull and Duration of Amnesia (Hospital Cases only)*

* Death due to causes other than head injury.

admitted to hospital; and (3) those whose injury is so slight that the motor-cyclist is not taken to, or is not detained in, hospital. Our information on the first and third groups is meagre. In the hospital cases there is a very significant difference between the motor-cyclists who were wearing crash helmets and those who were not (Table III).

Fractures.—Fractures of the skull are less frequent: as shown in Table III, of the patients admitted to our hospital in the acute stage only 32% of those wearing crash helmets had a fracture of the skull, as compared with 63% of those not wearing crash helmets. That the subacute and chronic cases do not confirm this finding is probably due, at least in part, to the fact that in those who wore a crash helmet our ability to find fractures long after the injury was considerably increased by knowing, from the marks on the helmet, where to look for them by means of further radiographic examinations.

Such fractures as do occur when a crash helmet is worn are probably much less severe than they would otherwise have been; for instance, the fracture may be fissured instead of depressed, as is perhaps exemplified in Case 4. In this hospital's series of injuries involving the frontal and ethmoidal sinuses, which have been collected by Major C. A. Calvert, there are 34 cases in which it is known whether or not a crash helmet was worn (Table IV). Among those who did not wear a crash helmet severe fractures of the inner table of the skull are common: as the table shows, there are examples of cerebrospinal rhinorrhoea, intracranial aerocele, meningitis, brain abscess, aneurysm of the internal carotid artery, lesions of the optic nerve or chiasm, and displacement of the orbit—in fact, most of the severe complications of extensively depressed fractures involving the frontal and ethmoidal sinuses. The patients who wore crash helmets were all free from these complications, with a corresponding improvement in the after-results. It is true that the chances of a patient being sent from a distance to this hospital are greater if he has one or more of the complications mentioned above than if he has none of them; but there is no selection as between those who have worn crash helmets and those who have not, and the most reasonable explanation of these figures is that the crash helmet is effective in preventing fractures of the frontal sinus from becoming depressed, from spreading widely, and from tearing the overlying dura, events which comprise one of the most important causes of morbidity and mortality among injured motor-cyclists. But to exercise this effect the helmet must come well down over the forehead, and, in view of the number of motor-cyclists who wear helmets which are too small for them, it is rather surprising that the results shown in Table III appear to be so uniformly favourable to the crash helmet.

Totals	24	10

* Owing to malunited fracture of lower limb.

Concussion.—In those patients who were wearing crash helmets, concussion, as measured by the duration of amnesia, was milder than in those who were not. As Table III shows, there is a significant reduction in the length of the amnesia: taking the acute, subacute, and chronic cases together, among the 208 cases in which no crash helmet was worn there were 44 (22%) with an amnesia of more than 7 days' duration; while among 72 cases in which a crash helmet was worn there were only 5 (7%) with an amnesia of more than 7 days.

Hence crash helmets cause a significant change in the percentage of fractures and long amnesias in those patients who come into hospital. The severity of injuries in a hospital population is not an easy thing to alter, and the fact that a detectable alteration has occurred implies that crash helmets have had a profound effect on the severity of injuries on the road. Unfortunately, it is not possible to give a mathematical "proof" that this alteration in severity has been in the direction of making the injuries milder, but common sense tells one that in most directions the change must have been for the better.

Some indirect quantitative evidence as to the effectiveness of crash helmets comes from a comparison between the two types of helmet. In the patients whom we have observed in hospital the distribution of the two types of helmet has been approximately equal (37 pulp and 35 vulcanized), but throughout the Army in this country during the period under investigation the issue of pulp and vulcanized helmets has been in the proportion of 2:1. The reasonable explanation of this is that half the accidents in wearers of pulp helmets were made so much milder than they would have been if a vulcanized helmet had been worn that the patient never came into hospital. The alternative explanation, that the pulp helmet made the accident so severe that half its wearers died before they got to our hospital, is rejected on the grounds that (*a*) the pulp helmet is the better helmet of the two (see below), and (*b*) such an enormous increase in the death rate would be easily seen from the figures of deaths to all motor-cyclists from all causes; these have, in fact, shown a decline since the introduction of crash helmets. No deductions can be made from this decline alone, since it is influenced by so many factors.

The estimate that the pulp helmet alleviates one-half of the injuries to such an extent that the dispatch rider does not require to go to hospital is a minimum estimate, based on the assumption that the vulcanized helmet had no effect in increasing or alleviating injury. But if, as we have reason to believe, the vulcanized helmet is of considerable use, this is an under-estimate of the effectiveness of crash helmets.

Using the minimum figure—that the pulp helmet saved one-half of its wearers from hospital—we can return to the data of Table III, which show that of the 72 hospital patients of all kinds wearing a crash helmet only 16 (22%) had an amnesia of one day or more, whereas of the 208 hospital patients not wearing a crash helmet 98 (47%) had an amnesia of one day or more. If we combine these facts with the supposition that there were at least another 37 pulp-crash-helmet accidents in which the riders never came to hospital because their injuries were so much reduced by their helmets, we obtain the result that the severe amnesias in 100 crash-helmet accidents number only about 15, at most, whereas in 100 non-crash-helmet accidents they number 47. We therefore deduce that the present helmets have reduced the severe amnesias to at least one-third of what they would have been.

Comparison of Types of Helmet

For a direct comparison of the two types we can use our figures for the total number of crash-helmet cases, which include many that did not come to this hospital and in which, since information was sought from all sources, there is a high proportion of fatalities. There were 52 of each type. Table V shows that in the vulcanized helmet group the outer shell is broken with much greater frequency, and skull fracture in cases coming into hospital is nearly twice as common. On the basis of these figures and those of the general distribution of the two types of helmet we may conclude that as regards prevention of fractures of the skull the pulp helmet is about four times as good as the vulcanized. If the vulcanized helmet were of no use in preventing fractures, then the pulp helmet would reduce fractures to one-quarter of their former incidence.

TABLE V.—*Comparison of the Two Types of Helmet*

Type of Helmet	Total	Fracture of Helmet Shell	Fracture of Skull	Deaths	Remarks
Vulcanized ..	52	43	23	5	All due to head injury
Pulp	52	18	12	5	4 died of injuries to parts other than head

There is no significant difference in the duration of amnesias in the two groups of cases. But for this comparison our figures are rather small. However, if we suppose that the serious amnesias in the two groups are in fact equal, then, since there are twice as many pulp helmets as vulcanized helmets in use, the serious amnesias per accident are twice as great in the vulcanized group as in the other.

Conclusions

In all, 106 examples of head injury in motor-cyclists wearing crash helmets have been examined.

The site of the blow on the helmet and the injury to the underlying scalp and skull correspond.

Over 50% of the blows are on the front of the helmet. The least common site of injury is the crown of the helmet.

Blows on the occipital region are least dangerous and those on the temporal region most dangerous to life. Blows on the crown may be associated with crush fractures of the vertebrae.

In 40% of the cases the head receives more than one blow.

In motor-cyclists it is very rare that brain injury results from a blow limited to the face.

The crash helmet is effective in diminishing local damage to the brain and its coverings at the site of impact, and it tends to lower the incidence of cases of prolonged amnesia.

Though our figures are rather small they suggest: (*a*) that the incidence of fractures of the skull is quartered by the better (pulp) type of helmet: the severity of those that do occur is less; (*b*) the incidence of prolonged amnesia (one day or more) is only one-third of that in accidents in which no crash helmet is worn; (*c*) in non-lethal accidents the pulp crash helmet so alleviates the injury that one-half of the dispatch riders who without its protection would have to go to hospital do not need to do so.

Of the two types of crash helmet in common use the pulp helmet is superior to the vulcanized rubber helmet.

Further improvements in the design of helmets offer a profitable field of preventive medicine.

We wish to acknowledge assistance from those officers mentioned in the text, also from Lieut.-Col. G. O. Chambers, *M.C.*, and the officers of a Military Hospital for Head Injuries—in particular Major W. Ritchie Russell; Brig. H. E. Rance, O.B.E. (Royal Signals); Col. E. R. Cawdron (Claims Commission); Col. F. P. Vidal, C.B.E. (Southern Command); Major C. Cassidy, *M.C.*; Major Patrick Clarkson, R.A.M.C.; Capt. Harold Elliott, R.C.A.M.C.; Sir Edward Penton (Chief Inspector of Clothing); Lieut.-Col. J. A. A. Pickard, D.S.O. (Royal Society for the Prevention of Accidents); and Mr G. F. Rowbotham. The clinical notes on which this investigation was based were maintained by a grant from the Medical Research Council.

A practical example of rehabilitation was mentioned at the sixty-third annual meeting of the Mental After-Care Association. The superintendent of one of the homes for convalescent male patients arranged with a local factory doing war work of much importance, first to train him in some semi-skilled processes with light and portable material, and then to send such material to the home in order that he might teach the patients to work upon it. Although this experiment was started only towards the close of last year, already the finished work sent back to the factory by the patients has greatly exceeded the firm's expectations alike in its accuracy and in the speed with which it has been done. Even more gratifying is the beneficial effect apparent in the patients. Their conversation at table is no longer about nerves and insomnia, and the reflection that they are taking some active part in the national effort is a great stimulus to their conversation, self-respect, and mental health. Col. Henry Yellowlees, chairman of the association, said at the meeting that the original object with which the association was founded was curative work, and the council had aimed at turning ex-patients into useful citizens, constructing a bridge over which the patients might pass from the restraints and seclusion of mental treatment to the freedom of responsible working life. Mr R. Sargood, chairman of the Mental Hospitals Committee of the L.C.C., said that his council had no intention of doing this work itself, but was content to leave it in the hands of the association. The Bishop of London also supported the objects of the association (of which 13 bishops are vice-presidents), and spoke of the function of the pastoral office in helping people to regain mental health. During last year the association dealt with 2,500 patients, of whom over 1,000 were sent to the homes.

THE DIET IN DIABETES

BY

R. H. MICKS, M.D., F.R.C.P.I.

Physician, Sir Patrick Dun's Hospital, Dublin; Consulting Physician, Royal Victoria Eye and Ear Hospital

Recent correspondence in the *Journal* has shown that some physicians are doubtful about the necessity for accurate dietetic control in the treatment of diabetes; it follows that they must be prepared to doubt the importance of maintaining the diabetic's blood sugar at a level near to normal. To all those who share this scepticism and to all those who are interested in the study of their less docile diabetic patients I offer, in full consciousness of all that I have still to learn, this short summary of my experience, conclusions, and practice.

Early in my experience as a physician, nearly 20 years ago, I found that it was possible to maintain excellent health and vigour in those rebellious severe diabetics who refused to follow any regulated diet, no matter how liberal it might be. Some of them made no secret of their refusal to follow directions, but others tried (often successfully) to pass themselves off on their doctor as model patients. About 12 years ago I began to approve of the abandonment of strict dietetic control for those patients who found that they could succeed in maintaining a sugar-free urine only at the cost of hypoglycaemic attacks. Finally, during the last eight years I have never (except in the case of diabetes of very recent onset) advised a diabetic patient to eat a regulated diet, and I have often transferred a conscientious but worried patient from controlled to uncontrolled diet without deterioration in his condition. At the present time none of my diabetic patients are on a controlled diet.

General Principles of Treatment

My experience has been that in all cases of diabetes seen by me the maximum attainable degree of health and vigour could be maintained despite a persistently high blood sugar. The chief aim of diabetic treatment seems therefore to be not a sugar-free urine or a low blood sugar but the maintenance of the patient in health and vigour. This can be accomplished in severe diabetes only by insulin. The object of regulation of meals should be not the maintenance of a carbohydrate balance but the avoidance of hypoglycaemic attacks. Glycosuria implies a regrettable waste of good foodstuffs, but an abundant glycosuria is not incompatible with sustained health and vigour.

Overriding all rules should be the maxim that the right line of treatment for each individual diabetic is that line of treatment on which he is best able to maintain health and vigour over a prolonged period. A lifetime of study may be necessary to make sure that years of apparent good health do not conceal the insidious development of arteriosclerotic or degenerative processes. For that reason I make a plea for the prolonged study of the group of persistently hyperglycaemic (but otherwise healthy) diabetics, for in this study lies the final justification or refutation of the need for strict dietetic control.

Insulin

Insulin in solution is usually given in preference to insulin suspension, the chief reason for the preference being that it demands less complicated instructions as to the prevention of hypoglycaemic attacks. In most cases of severe diabetes in adults two injections daily are found to suffice, but in many children a third (evening) injection is required to prevent a morning ketosis. The total daily dose varies with different cases between 10 and 60 units. If the dose is too low polyuria will probably attract the patient's attention, the urine at some periods of the day will contain ketones, and the weight will fall. If the dose is too high hypoglycaemic attacks will occur in spite of the fact that the patient is eating freely and frequently.

Patients are taught to weigh themselves often and to report at once any substantial change of weight. They are also taught that an illness of any sort (especially a pyrexial illness or an illness accompanied by vomiting or dysphagia) must be looked on as a serious threat to life entailing probably immediate admission to hospital.

Diet

The first rule taught to a diabetic is that, while no harm follows an occasional omission of the insulin injection, very grave harm will follow if insulin is injected and no accompanying meal taken. This warning makes it clear to him what he should do if compelled by emergencies to miss a meal. The second rule is that a small carbohydrate meal, which need be no more than a hunk of bread, should be taken between each of the three chief meals of the day. The diabetic taking insulin at breakfast and after his midday meal should always have something more to eat in the middle of the morning and in the middle of the afternoon. This rule safeguards him from occasional attacks of hypoglycaemia, especially those which occur from inevitable postponement of one of his chief meals. The third rule is that unwonted bodily exertion should always be followed by ingestion of a little carbohydrate. This precaution is particularly important for those engaged in intermittent heavy manual work or in athletics.

When the patient is first admitted to hospital the state of coma or severe ketosis so often present on admission is corrected, and then he is allowed to eat as he likes. The calorie content of his diet is calculated in order to observe (and if necessary correct) any marked eccentricities of personal taste, and to make sure that it is not inadequate. As a rule two daily injections of insulin of from 10 to 30 units each are given, and this trial dose is increased if there is not a steady gain in weight or if ketosis appears. Usually at some period the patient (unless elderly) is deliberately allowed to experience a mild hypoglycaemic attack.

Urine-testing is never taught, and those patients who insist on testing their urine are cautioned that a sugar-free urine may be a warning of hypoglycaemia.

Most of my patients eat a diet with a high carbohydrate and a minimal protein content. Gluttony is almost unknown. Many are engaged in fairly heavy manual work and have very irregular hours of duty.

Coma

No clinic has been able to produce statistics of recovery so good as those of Joslin, and his doctrine of plenty of insulin and plenty of intravenous saline summarizes, I am convinced, the decisive measures in the treatment of coma or threatened coma. During the first few decisive hours of treatment insulin and saline are administered in amounts dependent on the rate of improvement in the patient's mental state, respiration, and circulatory condition. During these few hours there is little risk of hypoglycaemia. But if the dosage of insulin has been high hypoglycaemia may readily occur at a later stage, for the duration of effect of a large dose of insulin is much longer than that of an ordinary maintenance dose.

I have found that, once the acute stage of coma has been corrected, there is nothing to be feared from the free administration of glucose in amounts considerably above what is required to prevent hypoglycaemia. Coma must often be treated without facilities for blood-sugar estimations, and it seems to me that the permission to administer glucose freely is an essential simplification of treatment; the physician cannot allow himself to be in the position of feeling uncertain whether cerebral disturbances are due to ketosis or to hypoglycaemia. The young doctor must be taught that it is the profound metabolic disturbance in which untreated diabetes culminates that is the cause of coma, and not the accompanying hyperglycaemia; otherwise he may well look on the precautionary administration of glucose to a patient under treatment for coma as a dangerous procedure, or, even worse, may hesitate to give heroic doses of insulin for fear of a hypoglycaemia which he may not succeed in controlling.

Children

The problem of managing the diabetic child is obviously simplified by allowing frequent feeds of normal composition and administering insulin often enough and in large enough doses to prevent ketosis and achieve a gain in weight. But in one important respect the position as regards dieting in children is different from that in adults. Any child, whether diabetic or not, may overeat grossly on occasion, filling his stomach till he vomits. Such "gorges" in the diabetic child are usually the cause of a stormy attack of coma, not, I suspect, provoked by the absorption of too much carbohydrate but by the vomiting. My impression is that the diabetic child to whom the tasty foods of normal children are not forbidden is less likely to indulge in occasional outbreaks of gross gluttony than the controlled diabetic, but if he does indulge he will suffer for it just as certainly.

Acute Diabetes

It is possible that occasionally diabetes is seen at so early a stage that prompt treatment will avert degenerative changes in the pancreas. Though of course it is not easy to prove that the rare cases of complete recovery under treatment might not have recovered spontaneously if untreated, it is obviously wise in all cases of very recent onset to insist on complete rest in bed and very careful control of the blood sugar by means of insulin and a measured diet; only when the passage of time has made it clear that the condition is an established one should the patient be allowed to resume normal activities and an uncontrolled diet.

The Mild Diabetic

By a "mild diabetic" is meant a patient who is able to maintain as high a level of health and vigour without insulin as when taking insulin. Putting aside the regulation of the diet for such conditions as obesity, my experience is that these patients, the elderly, the obese, the arteriosclerotic, and the hypertensive, are none the worse for a high blood sugar. I am very doubtful of the wisdom of restricting the intake of the mild diabetic. In some such patients a sugar-free urine can be achieved only at the cost of under-nutrition. Yet such patients, if allowed a normal diet, may lead an active life without the help of insulin. The borderline patients, who can live without insulin but are better on insulin, sometimes insist on dropping it for a spell. It is my experience that, when they do this and later consent to start injections again, their (small) insulin requirements are not increased by the period of omission.

It is of course important to warn every mild diabetic of the possibility that acute intercurrent illness may bring about a rapid change for the worse and precipitate diabetic coma.

Complications

When the complication is one the danger of which lies in its tendency to provoke coma—e.g., septic infection—the same line of treatment which is successful in the treatment of coma may be applied to its prevention. When the diabetic has to undergo a major surgical operation the physician's attention should be directed not towards keeping the blood sugar low but towards averting ketosis. Tuberculosis is, in my experience, neither more nor less difficult to treat than in the normal subject.

The aetiology of the retinitis, the cataract, and the arterial thickening so common in elderly diabetics is still unknown. There is not, I think, any evidence as to whether such complications are commoner in patients with persistent hyperglycaemia than in the controlled group. But the evolution of these lesions, once they have appeared, does not seem to be affected by the level of the blood sugar. In so-called diabetic gangrene the level of the blood sugar does not appear to have any effect on the progress of the lesion.

Discussion

Against the conclusion which I have drawn from the sustained good health of diabetics whose diet is not controlled—namely, that adequate insulin dosage and the avoidance of hypoglycaemia are the only essentials in the treatment of diabetes—several arguments may be advanced.

1. It may be argued that the health of my patients would have been still better if their blood sugars had been lower. In reply to this it should be noted that the change from a

measured to a free diet has often been made without deterioration in health or vigour.

2. It may be argued that the patients believed to be eating an uncontrolled diet were in fact unconsciously eating a diet which maintained a fairly accurate carbohydrate balance. This is not so.

3. It may be argued that the insulin requirements of my patients are greater than they would be on a measured diet. This may be so, but, as none of my patients need more than 60 units a day and the majority take between 10 and 40, the point is not very important. (This point would be important if it could be shown that cases of established diabetes under control gradually progressed towards complete cure. This question has already been dealt with in the paragraph on acute diabetes.)

4. It may be argued that in 20 years' time the fate of the surviving uncontrolled diabetics may be worse in respect of late complications than that of the controlled group. That is certainly possible. It is no answer for me to claim (as I do) that over 10 years' observation reveals no evidence of premature arteriosclerosis, for it may be that in the development of late diabetic complications there is a clinically silent stage analogous to that in the development of syphilitic aortitis.

If it were not for this objection I would have no hesitation in proclaiming that the maintenance of a carbohydrate balance was an unnecessary adjunct to the treatment of diabetes. But time will settle the question. Twenty years have already elapsed since the isolation of insulin, and soon many young diabetics treated in the first decade after its introduction to therapeutics will be reaching middle age. It will then be possible to judge between the rebellious and the docile, and for that very reason I wish to repeat my plea for a continued careful observation of the former class.

Summary and Conclusions

A plea is made for the study of the group of severe diabetic patients who refuse to follow any regulated diet but will take insulin. Prolonged study of these uncontrolled but otherwise healthy diabetics will show whether their persistent hyperglycaemia favours the onset of arteriosclerotic or degenerative complications. Observations during a period of over ten years yield no evidence that it does so.

Study of this group has convinced me that regulation of the diet with a view to maintaining a normal blood sugar is unnecessary; this opinion is based solely on the sustained good health of patients on uncontrolled diet. The patient must take enough insulin to prevent ketosis, and arrange his meals so as to avoid hypoglycaemia. If he does this his condition is not improved by maintaining a carbohydrate balance. The mild diabetic who does not require insulin does not benefit (unless obese) from strict dietetic control.

In diabetes of very recent origin it should, however, be assumed that accurate dietetic control will favour whatever chance of complete cure may exist.

Normal (uncontrolled) diet in the child is not associated with frequent attacks of coma. Outbreaks of gluttony in the diabetic child are dangerous and lead to coma, not because they produce hyperglycaemia but because they are followed by vomiting.

In the treatment of coma insulin and intravenous saline are the two essentials. If at any stage the onset of hypoglycaemia is feared, then glucose can be administered freely and without blood-sugar control.

Two grants of £1,000 each have been made by King Edward's Hospital Fund for London to assist in the establishment of two group preliminary training schools for nurses—one at Hampstead to serve a North London group of hospitals, and the other at Blackheath to serve a group south of the river. Additional financial help will be given during the next three years should such further help be necessary. The King's Fund is prepared to consider similar schemes by other groups of hospitals in its area and to make grants up to a total of £5,000 for this year, with assurance of continued help for three years in case of need. Further particulars may be obtained from the Nursing Recruitment Centre, 21, Cavendish Square, W.1.

TREATMENT OF ASTHMA BY NICOTINIC ACID

BY

G. MELTON, M.D., M.R.C.P.

Late Senior Resident Physician, Lewisham L.C.C. Hospital; Physician, Dudley Road Hospital, Birmingham

Maisel and Somkin (1942) have recently published a preliminary report on the treatment of the asthmatic paroxysm with nicotinic acid. Relief of the paroxysm was obtained in 21 out of 30 cases treated with the drug, either by intravenous injection (16 out of 21 patients relieved) or orally (5 out of 9 patients relieved). Eighteen patients who had received intravenous therapy were subsequently given the drug orally, and 11 of these cases were definitely improved. Neuwahl (1942), who had obtained satisfactory results with the drug in angina pectoris, also used it in 7 cases of asthma in order to note its action on smooth muscle. Of his patients 4 were improved and 3 were made worse. It is not known whether the drug acts by relieving bronchospasm or by affecting the pulmonary vessels, or whether it is converted into or liberates another substance which is the physiologically active agent. Neuwahl suggested a pharmacological similarity to histamine; but, as Maisel points out, this does not appear to explain its action in asthma.

For some months before either of these reports came to my notice I had been treating asthma with nicotinic acid, both during the paroxysm and between the attacks. It was hoped that its action in dilating blood vessels might be accompanied by a similar action on the bronchioles.

Treatment of the Paroxysm

Of 19 cases which received treatment during the paroxysm 7 had had slight or no relief from adrenaline or had relapsed. Most of the attacks treated were severe ones. The possibility was considered that improvement following the treatment might be due to psychological influences associated with coming into hospital and receiving injections, and an attempt was made to control this factor by giving an intravenous injection of sterile water, preferably before nicotinic acid, to 12 of the cases. In some instances a control injection was given in a later attack. The effect of the control injection was then compared with that produced by nicotinic acid. Slight transitory improvement was noted in 7 cases after the use of sterile water. Two patients not included in this series had their attacks completely relieved though they did not receive nicotinic acid. In order to be sure of a rapid action, nicotinic acid was as a rule given intravenously in doses of 50 mg. (half those used by Maisel). One ampoule was dissolved in 10 c.cm. of sterile water and the injection was given very slowly. Two cases received intramuscular injections, and in one of these the dose employed was 100 mg. One case received 50 mg. intravenously and 50 mg. intramuscularly. A second intravenous dose was given to many of the patients during a relapse or a succeeding attack, sometimes within a few hours of the first dose. Six cases, 4 of which had already received nicotinic acid intravenously, were given the drug orally in doses of 50 or 100 mg. (1 or 2 tablets) during a paroxysm.

Results.—The effect of nicotinic acid in 16 of these patients was to produce definite improvement in at least one of the attacks for which the drug was given. In 8 cases the relief was practically complete; in the other 8 there was a residual wheeze for many hours. In all cases adventitious sounds persisted in the lungs—a fact noted by Maisel. Improvement usually began to manifest itself within a few minutes of the injection, the patient falling asleep in many instances and awaking the next morning much relieved. The duration of relief varied considerably and did not always appear to be dependent upon further doses, parenteral or oral. The period of relief was sometimes as short as half an hour, but in other cases there was no further attack for some days, even when the attacks had been frequent before admission. On the whole a relief of several hours was obtained. Further injections sometimes repeated the improvement resulting from the first one, but in 5 cases later injections resulted in little or no relief. This suggests that in some instances the efficacy of nicotinic acid is affected by repeated use, contrary to what is stated by Maisel. It is of course possible that the smaller dosage employed by me might in part explain this difference. Two cases were not improved at all by nicotinic acid. Neuwahl refers to severe exacerbations of asthma which occurred in 3 of his cases. This effect was also seen in 2 cases of this group. One case developed a status asthmaticus 24 hours after an intravenous injection which had given considerable relief and had been followed 20 hours later by an oral dose.

Flushing, tingling, and a feeling of heat appeared within a few minutes of the administration of nicotinic acid, and these symptoms were often pronounced and preceded improvement of the asthmatic attack. Occasionally headache, giddiness, depression, palpitations, and increased tightness of the chest were noted. As Maisel observed, improvement sometimes follows a bout of coughing.

Treatment between the Attacks

In 30 cases, many of which had severe and frequent paroxysms not controlled by ephedrine or stramonium, nicotinic acid treatment was given between the attacks for periods varying from a few weeks to several months. Of these patients 11 had received treatment previously during an acute paroxysm. The drug was given orally generally in doses of 50 mg. two or three times daily. Some cases received 100 mg., particularly on retiring. Children usually received half these doses. It should be noted that Maisel employed oral doses of 200 mg. 3 times daily before meals and once on retiring, but no mention is made over what period such dosage was given.

Results.—The results from this treatment were on the whole favourable. Sixteen cases showed definite improvement as compared with their recent condition before beginning nicotinic acid. This improvement was characterized by a definite reduction in either the frequency or the severity of the attacks and often by both these factors. The period of improvement varied considerably, from a few weeks to several months. Ten other cases showed slight improvement, assessed on the basis of a reduction in the frequency or severity of the attacks or upon the fact that relapse occurred within two weeks of starting treatment. In 4 cases no material change resulted from nicotinic acid therapy. In 9 cases courses of nicotinic acid were alternated with courses of citric acid tablets, the latter acting as a control. The patients were not informed that any change over to different tablets had been made.* In 6 of these cases the effect of nicotinic acid was definitely superior to that produced by the control tablets, the patients generally showing an early relapse when receiving the latter. Two cases, however, were maintained on the control tablets for many months with infrequent attacks. Six cases relapsed rapidly when they were taken off nicotinic acid and received no treatment.

Flushing and the other symptoms produced by nicotinic acid were often present in this group, and two patients abandoned their treatment because of unpleasant effects. It should be noted that several patients in whom the effect of nicotinic acid had worn off responded subsequently to adrenaline and ephedrine, but some were refractory to all treatment.

Conclusions

These results on the whole confirm those of Maisel and Somkin that nicotinic acid appears to be of value in the treatment of the asthmatic paroxysm. The drug when given over long periods also appears to be useful in diminishing the frequency and severity of the attacks. It is necessary to be cautious, however, in assessing the value of any treatment in this condition with such irregular incidence of attacks and susceptibility to psychological influence. Improvement after control injections and tablets illustrates this point. Nevertheless, in the majority of cases in which control therapy was employed, nicotinic acid proved much superior to the control measures in relieving the paroxysms and reducing their frequency. In view of the larger doses given by Maisel and Somkin, it would certainly seem an advantage to increase the dosage above 100 to 200 mg. daily in those cases which do not improve. Yet, although the drug appears to be non-toxic, it can on occasion produce unpleasant symptoms, and the possibility of an exacerbation of the asthma (not noted by Maisel) must be borne in mind. I agree with Maisel and Somkin that at present nicotinic acid should only be regarded as an adjuvant in the treatment of asthma, particularly when adrenaline and ephedrine are proving ineffective or when ephedrine cannot be taken because of toxic symptoms. Further trials with the drug are obviously necessary.

Summary

Nicotinic acid was given to 19 cases of asthma during one or more acute paroxysms in doses of 50 or 100 mg., as a rule intravenously. Definite improvement was obtained in 16 cases. Two cases had marked exacerbations. Control injections of sterile water were usually much less effective.

The drug was given over a long period in 30 cases, 11 of which had already received intravenous therapy. The frequency and severity of the attacks were definitely reduced in 16 of these. The doses used were 50 or 100 mg. 2 or 3 times daily. Half these doses were administered to children. The cases which improved on the drug frequently relapsed when it was discontinued or when they were receiving control tablets of citric acid.

I would like to thank Dr. W. Allen Daley, Medical Officer of Health to the London County Council, for permission to publish this report.

MENINGITIS DUE TO DIPLOCOCCUS MUCOSUS*

BY

P. T. BRAY, B.Sc., M.B., B.Ch.
Capt., R.A.M.C.

AND

J. C. CRUICKSHANK, M.B., Ch.B., D.T.M.

(From a Military Hospital and the Emergency Public Health Laboratory, Exeter)

McFarlan (1941) has recently described the characters of a capsulated Gram-negative diplococcus which had been isolated from the purulent cerebrospinal fluid of a young man. The man had been first seen on account of bed-wetting and slovenliness, and was found to have scanning speech and intention tremor. Pyrexia and signs of meningitis supervened, but he made a rapid recovery after sulphapyridine treatment. The organism was identified as *Diplococcus mucosus*, originally described by von Lingelsheim (1906, 1908) and isolated by him from the nasopharynx and cerebrospinal fluid. Cowan (1938) had described similar strains isolated from the cerebrospinal fluid of patients after operation for cerebral tumour.

While there is considerable evidence that certain of the nasopharyngeal Neisseria may under favourable conditions give rise to meningitis, the pathogenicity of the capsulated diplococci for man has not been conclusively proved. It therefore seems of interest to report a case in which the causative organism was almost certainly *Diplococcus mucosus*.

Clinical Features

The patient, a man aged 29, with two years' military service, is a driver attached to a field ambulance. On May 24, 1942, he developed a slight sore throat, and the next day a pink macular and papular rash was noticed on the trunk. His throat improved, but he felt vaguely out of sorts during the whole week and the rash persisted. There was no fever during this period.

On May 31 he became suddenly ill with severe frontal headache, pains in the back and limbs, and fever. On admission to hospital a few hours later the temperature was 102° F. and pulse 100. The patient was confused and restless, and complained of intense headache. A profuse pink maculo-papular rash was present on the chest, abdomen, upper part of back, and proximal part of the limbs. No petechiae or purpuric patches were seen. Neck rigidity was present, but Kernig's and Brudzinski's signs were negative. A left divergent strabismus and left-sided ptosis were present, but it was subsequently found that the strabismus had existed since childhood. The pupils were dilated but reacted normally to light. Abdominal and plantar reflexes were normal. There was a leucocytosis of 12,400. Lumbar puncture soon after admission yielded a turbid fluid under increased pressure.

---

* The absence of flushing, etc., with citric acid did not appear to be regarded by the patients as indicating a change of treatment.

* A report to the Medical Research Council.

Sulphapyridine was given by the mouth, the initial dose being 2 g. Oral administration was satisfactory, and 9 g. were given in the first 24 hours. The patient rapidly became quieter, and the temperature had fallen to 99.4° F. by the following morning. The general condition was better, the headache less severe, and the mental state normal. The rash had almost completely faded, but petechiae were noted on the anterior aspect of the legs and there was a circular purpuric patch an inch in diameter on the right calf. The ptosis persisted and neck rigidity was still present, but Kernig's sign was negative. Lumbar puncture again yielded a turbid fluid; the pressure was normal. Sulphapyridine was continued in a dosage of 1 g. every 4 hours.

Improvement continued, and during the next few days the rigidity, ptosis, and headache abated. The dosage of sulphapyridine was decreased and the drug was discontinued on June 5, a total of 22 g. having been given. A slight right otitis externa, noticed on June 8, responded quickly to treatment. Convalescence was rapid, and no abnormality was detected on routine examination on June 14.

Laboratory Findings

The cerebrospinal fluid obtained on May 31 was turbid. There were 330 cells per c.mm., mainly polymorphs; protein 240 mg. per 100 c.cm. Fair numbers of Gram-negative diplococci were present, sometimes intracellularly. The opposed sides of the cocci were flattened, but the organisms were on the whole rather larger and more irregular in size than meningococci. Culture of the deposit on blood agar aerobically produced in 24 hours a profuse growth of yellowish mucoid colonies consisting of encapsulated Gram-negative diplococci. The characters of these organisms were as follows:

Morphology.—Gram-negative cocci occurring in pairs with the opposed sides flattened. A capsule was demonstrated by nigrosine and Muir's method.

Growth in Broth.—Diffuse turbidity in 24 hours at 37° C. aerobically.

Agar and Blood Agar, 24 Hours Aerobically.—Abundant growth of low convex, opaque, greyish-yellow round colonies, 2 to 3 mm. in diameter, smooth surface, entire edge, mucoid consistency, undifferentiated. There was no true haemolysis, but the blood underwent a brownish discoloration. Growth was slightly better at 37° C. than at 22° C.

MacConkey's Agar, 24 Hours Aerobically.—Good growth of similar colonies, tending later to develop an effuse periphery and a finely crenated edge.

Gelatin Stab.—Growth along the line of the stab and on the surface. No liquefaction in 3 weeks.

Biochemical Reactions.—Acid, without gas, was produced in glucose in 24 hours, but not in lactose, mannite, sucrose, or dulcite. Litmus milk was unchanged, indole was not produced, and the M.R. and V.P. reactions were both negative.

Pathogenicity.—1 c.cm. of a 24-hour broth culture was injected intraperitoneally into a guinea-pig without effect.

The cerebrospinal fluid obtained on June 1 was still turbid and contained smaller numbers of pus cells, but no organisms were seen in direct films. No growth was obtained on culture. Protein was 80 mg., chlorides 700 mg. per 100 c.cm.

The organism agrees in all respects with the type A form of *Diplococcus mucosus* described by McFarlan, who has discussed the systematic position of these strains and suggests that they are probably variants of the *Neisseria pharyngis* group. Though the evidence points strongly to the present strain being the cause of the meningitis, it would have been more conclusive if the isolation had been made on more than one occasion. Response to sulphapyridine was so prompt, however, that no organisms were found in the second specimen.

We are indebted to the Director-General, Army Medical Service, for permission to publish this report.

MULTIPLE MUSCLE HERNIAE

BY

IAN D. KITCHIN, F.R.C.S.Ed.

Hon. Orthopaedic Surgeon, Royal Lancaster Infirmary; Consultant Surgeon, E.M.S.

AND

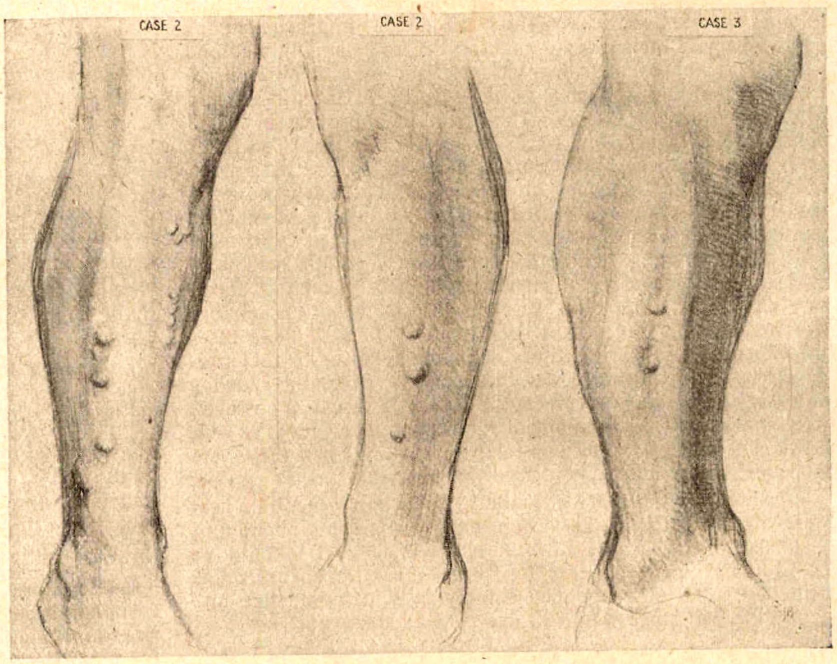
DAVID A. RICHMOND, F.R.C.S.

Resident Surgeon, Conishead Priory, Ulverston

Although from time to time one sees simple muscle herniae, usually of the tibialis anticus, they give rise to little comment, as frequently they cause only slight if any trouble. In most standard textbooks the subject is dealt with very briefly, and few references can be found to it in recent literature. The cases that have been described are mostly those of fairly large single hernia, but bilateral herniae of the tibialis anticus have been recorded.

Ihde (1929), in a comprehensive review of the literature, himself reports 12 new cases, but all those mentioned in the review, including his own, were either single or single bilateral herniae. No case of multiple or multiple bilateral herniae of the lower leg was mentioned. Neither have we been able to find any reference to this condition in later literature. We therefore consider the following three cases of multiple herniae of the tibialis anticus worth recording.

All three patients were soldiers and had been engaged in strenuous training in rough hilly country, and it seems possible that both the nature of the training and that of the country were contributing factors in producing the herniae. This is in accordance with the experience of Hesse (1921), who found muscle herniae rare except in mountainous districts, and of Pichon (Ihde, 1929), who found 39 cases in 217 Alpine soldiers, but only 1 in 1,000 Russian recruits. The herniae we have seen were small—about the size of a pea. All were reducible, and they disappeared when the muscle was contracted, leaving no palpable thickening. The splits in the fascia were distinctly felt. The openings were round and had quite sharp defined edges.



Records of Three Recent Cases

Case 1.—An infantryman was referred to hospital because of aching in both legs, which started during an intensive training course and was attributed to small varicose veins. Previously he had had no trouble, and was not a recent recruit. In addition to the varicose veins, three small reducible muscle herniae about the size of peas were present in the left leg, situated over the belly of the tibialis anticus muscle. The herniae were not tender, and disappeared completely on pressure and when the muscle was contracted.

Case 2 (illustrated).—This patient, an infantryman, was referred to hospital because of aching in both legs and both feet, attributed to varicose veins. He had had no previous trouble, was engaged in a course similar to that of Case 1, and was not a recent recruit. He had no varicose veins, but there were 13 small herniae of the right and 4 of the left leg, all situated over the tibialis anticus muscles. All were reducible, and all disappeared when the tibialis anticus muscles were contracted.

Case 3 (illustrated).—This patient was referred to hospital because of varicose veins. He also was an infantryman and not a recent recruit, and he complained of a "heavy feeling" of the right leg when running. This was first noticed two months previously after a football match, and at that time he observed a small swelling on the front of the leg. Recently he had been taking part in cross-country runs for the first time, and after one run noted the appearance of a second swelling. He had no varicose veins, but there were two small muscle herniae over the tibialis anticus, differing in no way from those in the other two cases.

Discussion

The pathology of muscle hernia is discussed at length by Ihde in his article, and there seems to be no reason why the origin of the small multiple herniae we have found should differ from that of the larger ones which he describes as due to severe strain, with hypertrophy of muscle and weakening and splitting of a previously deficient muscle fascia, as distinct from those which follow direct injury. The only condition with which these small herniae might readily be confused at first sight is varicose veins, but on closer examination the diagnosis is fairly obvious.

One reference only has been found to treatment of a small hernia in this region. Schmier (1937) describes the case of a runner with bilateral herniae over the tibialis anticus muscles, but he does not state the size of the swellings. However, as the man was first seen at a varicose veins clinic they were probably small. Both herniae were treated with repeated injections of sodium morrhuate. This allowed return to strenuous activity without discomfort for a year, when further injections were required to relieve the returning pain; it is doubtful, however, if this method would be suitable for multiple herniae. In the cases we have seen, apart from suggesting modification of duty, no treatment was advised, as the men complained of pain only after strenuous cross-country journeys; otherwise they were fit for all ordinary duties.

It may be that on account of their rarity these multiple small muscle herniae of the lower leg are of no great significance. On the other hand, having seen three cases within a few weeks in soldiers undergoing intensive training we considered them of sufficient interest to warrant a brief report.

Medical Memoranda

Mantoux Test versus Patch Test

Several papers have been published in recent years on the detection of tuberculous allergy by the patch test. In Monrad's (1936) series of positive Mantoux reactors 5% were negative to the patch test; in Wolff and Hurwitz's (1937) series 1.8%; in Vollmer and Goldberger's (1937) less than 1%; Hart's (1938) first series had 3%, and his second (1941) less than 2%, while Court's (1939) series had 2%. Camille Keresztur (1941), however, showed that 15% of his positive Mantoux reactors were negative to the patch test. It is advisable, therefore, to check up on these findings from time to time, and for this reason the results of an investigation seem worth recording.

INVESTIGATION OF 116 CASES

All the children admitted to the medical wards of a base hospital over a certain period were tested by the intradermal (Mantoux) and the percutaneous (patch) methods. The age varied from 6 months to 12 years. In the intradermal test 0.1 c.cm. of 1 : 1000 freshly prepared old tuberculin was injected into the skin of the forearm: this was sufficient to raise a wheal 8 mm. in diameter. The test was read 24 and 48 hours after injection, and was not considered positive if the resulting wheal or flare was less than 10 mm. in diameter. In carrying out the percutaneous test a tuberculin patch was applied to the chest wall between the scapulae and lateral to the spine after cleansing the skin with ether and allowing it to dry. The patch was removed after 48 hours, and the reaction was read 24 and 48 hours after the removal. Papules or a red flare, or any intermediate stage, were regarded as a positive reaction. The patches used were those of Messrs. Evans Sons Lescher and Webb. The following were the results:

Total number tested	116
Number negative to both tests	74
,, positive ,, ,, ,, ...	34
,, ,, to intradermal and negative to patch test ..	8
,, negative ,, ,, ,, positive ,, ,, ,, ..	0

There was one case of plaster dermatitis. In two cases the patch tests were negative after 24 but positive after 48 hours. These were considered positive reactions. Of the Mantoux tests 10 were apparently positive after 24 hours, but had faded to negative after 48 hours. These were recorded as negative reactions.

SUMMARY AND CONCLUSIONS

The intradermal Mantoux test and the tuberculin patch test were performed on 116 children.

The Mantoux test was positive in 8 cases in which the patch test was negative.

Both tests should be read 48 hours after being applied, to avoid false positives thought to be due to the erythema around the needle puncture. It is important to use a preparation of old tuberculin not more than three weeks old.

It seems likely that different observers employing patches of different make may get variable results. The intradermal method is less liable to diversity and is more reliable.

I am grateful to Dr. Wyllie for his interest in this investigation, and for permission to publish the series; also to the nursing staff for their helpful co-operation.

Convulsive Treatment of Climacteric Depression

Treatment of cases by electrically induced convulsions was begun in this hospital in March, 1942, and for the nine months ending Dec., 1942, we had the following results in female patients:

	Acute	Chronic	Total
No. of patients treated	43	17	60
Total No. of convulsions	945	349	1,294
No. of patients discharged	*30 (69·9%)	0	30

* Of this total 26 (60·6%) were discharged recovered and 4 (9·3%) were discharged relieved.

The average stay in hospital of all discharged cases was 5½ months—in recovered cases 5⅓ months, and in cases of involutional melancholia 4 months. The classification of these patients, the number treated, and the percentage rate of discharge in each class were:

Diagnosis	Number	Percentage Discharge
Involutional melancholia	25	68
Schizophrenia	19	31·5
Mania	3	100
Psychoneurosis	3	100
Other psychoses, including mixed types, puerperal confusion, and paraphrenia	10	30

The results in schizophrenia are poor. The 31.5% discharge rate noted in this group occurred in cases of very recent onset, and their clinical histories suggested the likelihood of remission with or without special treatment. The course of the illness noted under mania, psychoneurosis, and "other psychoses" seemed also to be unaffected by electrically induced convulsions.

As with other workers, our experience suggested that the best results are to be obtained in melancholia, especially of the involutional type. According to Jessner and Ryan (1942), "rather striking results have been reported in involutional melancholia." This is not surprising, since the case records indicate that climacteric depressives have the most favourable prognosis of our female admissions. It seemed important, therefore, to consider whether treatment by electrically induced convulsions shortened the length of stay in hospital.

The length of illness before the use of this method of treatment was approximately six months. In the group noted above the patients were discharged recovered after an average stay of four months. It would thus seem a reasonable inference that treatment by electrically induced convulsions accelerates discharge of mental hospital patients who are admitted suffering from recoverable depression. Whether this recovery is associated with a greater or less degree of permanence it is too early yet to determine. So far, however, the reduction of time lost in illness from six months to four makes a strong case for the value of this form of treatment for this particular type of case. It has, too, the advantage of comparative safety. In 1,300 convulsions there were only two minor accidents: one a dislocation of the jaw, and the other a subluxation of the shoulder-joint.

I wish to thank Dr. George Somerville, medical superintendent, West Ham Mental Hospital, for permission to publish these results.

Treatment of Intestinal Carriers of the Enteric Group of Organisms

The following note on the results of the use of sodium iodophthalein in enteric infections may be of interest.

CASE HISTORY

A girl aged 16 was admitted to the local fever hospital on Sept. 24, 1941, after an illness of ten days. She complained of abdominal pain with constipation. The temperature was 98.8° and the pulse 90. Some ten to fifteen typical "rose spots" were present over the chest and abdomen, and there were one or two on the back. The following day blood and faecal specimens were sent for bacteriological examination. The Widal reaction was positive to *Bact. paratyphosum* B infection, while the faecal specimen showed the presence of the same organism. Progress and convalescence were uneventful. Her stools, however, examined at weekly intervals, persisted in giving growths of the organism for 22 weeks despite the use of such drugs as hexamine, salicylates, bismuth c̄ salol, and vegetable carbon.

Reading of Saphir and Howell's (1940) successful treatment of a carrier of *Bact. paratyphosum* A with sodium iodophthalein (opacol), it was decided to try the effect of the drug on this carrier of *Bact. paratyphosum* B. The technique and dosage were identical with those used in *x*-ray examination of the gall-bladder. Two doses were administered, with an interval of a fortnight. The faeces remained positive after the first dose, but after the second dose three specimens taken at five-day intervals were returned negative.

The patient was discharged on March 13, 1942, after spending 24 weeks and 3 days in hospital—i.e., 26 weeks after the onset of the illness.

Since treating the above case I have had an opportunity of watching the effect of sodium iodophthalein in seven cases of *Bact. typhosum* infection. The essential points may be tabulated thus:

Case	Age (years)	Number of Weeks of Infection before Administration of Opacol	Number of Doses Required
1	38	10	2
2	11	14	1
3	13	15	1
4	17	10	2
5	8	10	3
6	23	7	2
7	54	5	2

All the patients were discharged after repeated negative stools.

COMMENT

The above is a method of treating medically intestinal carriers of the enteric group of organisms and should be tried before submitting the patient to any operative procedure.

Two doses of sodium iodophthalein are usually required.

The last two patients were members of the staff and were given the drug early in order that they might return to duty, thus saving man-power.

My thanks are due to Dr. S. K. Young, M.O.H., for permission to publish these cases.

R. CAILE, M.B., B.S.,
Deputy M.O.H., Durham City.

Reviews

SHOCK

Shock. Its Dynamics, Occurrence and Management. By Virgil H. Moon, M.Sc., M.D. (Pp. 324; illustrated. 21s.) London: Henry Kimpton.

Why the first use of the word "shock" in medicine should be "credited" to this person or that is a mystery: many workers in this field to-day feel that it would be more fittingly debited. Seldom has so much confusion been due to so small a word, and monosyllabic at that: ignorance is usually cloaked in polysyllabic Latin derivations. The ancients from their fleeting glimpses of the unicorn described it with the legs of a buck, the body and head of a horse, and the tail of a lion; but we are still uncertain whether they described one animal or three. Dr. Virgil Moon admits the confusion between "shock" and the effects of haemorrhage, but considers shock to be an entity. In this new book (which supersedes his previous monograph, *Shock and Related Capillary Phenomena*, published in 1938) he believes still that this fabulous concept may be caught in the net of yet another definition. An essential property for catching the unicorn was a virgin, before whom it would lie down and allow itself to be apprehended. The ancients ascribed their notable want of success to the difficulty of finding a virgin. Our own failure with the shock problem, though perhaps partly due to the entertainment of preconceived ideas, can be more properly ascribed to too little of the right kind of experience. Virgil Moon, however, has no lack of experience in this field, and in the space of 324 pages, with the help of 437 references, he tries to tame the animal.

The author discusses at length the role of anoxia, toxaemia, local loss of fluid, nervous stimulation, anaesthesia, and adrenal dysfunction in the genesis of shock, and points out that confusion arises on four main points: lack of knowledge of capillary physiology, failure to pursue pathological inquiries, unrecognized sources of error, and a belief in the identity of shock with the effects of haemorrhage. We would point out a fifth: the application of results obtained by animal experiment directly to man. For instance, he states (p. 262) that "haemodilution occurs *immediately* after haemorrhages," having previously cited two references to animal experiments. If this were so in man, it might be useful in differentiating haemorrhage from some types of "shock," but recent work has shown that it may not occur for several hours. A great deal of stress is laid on capillary pathology—14 out of 19 photographs depict the lung. There is at the moment an unparalleled barrage of investigation directed on the "shock" section of the research front, and many of the views expressed herein will doubtless have to be modified as a result. This in no way, however, detracts from the value of this monograph, which sets out clearly the present point of view of an experimental pathologist, and poses numerous points for energetic argument and examination, together with many useful references.

OPHTHALMIC TREATMENT

The Ophthalmic Prescriber's Codex. By Francis E. Preston, D.O.M.S. (Pp. 176. 10s. 6d.) London: H. K. Lewis and Co. 1943.

In the *Ophthalmic Prescriber's Codex* Dr. F. E. Preston brings together an imposing mass of prescriptions, a guide to treatment, and much pharmacological knowledge. The section dealing with prescriptions covers about one-third of the book and is a full ophthalmic pharmacopoeia interspersed with concise and useful information on dispensing. It is conveniently arranged, and its value is enhanced by the fact that it gives both metric and imperial weights and measures. As this section is probably the fullest ophthalmic pharmacopoeia available, its usefulness can hardly be questioned. Nor can there be any cavil at the concluding 50 pages of the book, which give in readily accessible form such despised but essential things as lists of abbreviations in common use, normal values of various body fluids, posological tables, lists of incompatible drugs, weights and measures equivalents with conversion tables, and much other information besides. There are specially valuable sections on buffered ophthalmic solutions and on the sulphonamides.

It is the middle section, dealing with treatment, that is open to criticism. Those who like tabulated lists of therapeutic measures will find this section exhaustive enough, but the reviewer would have liked more recognition of masterly inactivity and plain confession of therapeutic impotence. It is, however, only right to stress that the treatments suggested show a wide acquaintance with modern methods, and Dr. Preston no doubt meant this section to be a reminder rather than oecumenical.

NURSING IN THE TROPICS

Tropical Nursing. A Handbook for Nurses and Others going Abroad. By A. L. Gregg, M.D., M.Ch., B.A.O. Second edition. (Pp. 185. 6s.) London: Cassell and Co.

This handbook describes the symptoms, signs, and treatment of the commoner and more important tropical diseases from the standpoint of their practical nursing, the diseases being arranged in alphabetical order so that reference is easy. A section also deals with the technique of the simpler diagnostic and therapeutic procedures that a nurse in the Tropics may be called upon to carry out, for in the Tropics a nurse may have to do many things that at home would normally be performed by one of the junior medical officers. There is also a chapter on personal hygiene, which gives many useful hints to the nurse who may be about to take up her first appointment abroad.

The book is of convenient size, well printed, and free from serious errors. It will be of considerable value to those who—for example, now in military service—may be meeting tropical diseases for the first time, and to those whose work takes them to remote areas abroad where they will have to rely largely on their own knowledge, judgment, and initiative. It is moderately priced and should continue to enjoy its already well-deserved popularity among nurses dealing with tropical diseases.

Notes on Books

LANGDON-BROWN and HILTON'S book *Physiological Principles in Treatment* is now 34 years old, and reading it one has much the same impression as in reading *Hamlet*, that one has heard it somewhere else before. But this is really the highest praise one can give, for it shows that, as a result of this book and others of the same kind, the profession is now more physiologically minded than when Dr. Langdon Brown (as he then was) first wrote it. Indeed the very success of such books may diminish the demand for them. To-day the need is for a greater application of psychological ideas in medical treatment and for more applied physiology in the factory, the armed Forces, and in preventive medicine rather than at the bedside. There are one or two changes we should like to see in future editions. The newer alkalis, magnesium trisilicate, aluminium hydroxide, and aluminium phosphate, receive less attention than they deserve, and the biochemical basis of action of the sulphonamide drugs might have been more fully discussed. It is also doubtful whether wartime decreases in diabetes mellitus are due to restriction of carbohydrate, for there is a good deal to suggest that the incidence of diabetes is more closely correlated with the consumption of fat than of carbohydrate. These are minor criticisms, however, and the book is aimed at a worthy target. It does not make the mistake of Macaulay or the Americans of over-estimating the time and capabilities of the average student, and it tells him just as much as he ought to know if he is to preserve the physiological outlook through his first overwhelming clinical years. The publishers are Baillière, Tindall and Cox, and the price is 12s. 6d.

The appearance of the fifteenth edition of *Stedman's Practical Medical Dictionary* (London: Baillière, Tindall and Cox; 42s.) barely three years after its predecessor is clear evidence of the demand for this well-known reference book. In its preparation the editor, Dr. S. T. Garber, must have had a more than usually arduous task. Not only has the dictionary been brought up to date, but it has been entirely reset in a new type, chosen, after much deliberation and exhaustive tests, for its legibility and clearness—and that it possesses these qualities we certainly agree. The section on that ever-expanding subject the vitamins has been revised, and many new biochemical and chemotherapeutic substances are described. The entire terminology of the bacteria, too, has been revised to agree with the type-species concept incorporated in the International Rules of Botanical Nomenclature, and cross-references are made from the older to the newer titles. Fresh illustrations have been included and some old ones replaced. The introductory article on medical etymology will continue to appeal to the more literary-minded; and another useful section that has been retained is the nomenclature in Latin and English adopted by the Anatomical Society of Great Britain and Ireland, with B.N.A. equivalents. Those who do not allow themselves to be unduly disturbed by American spelling will welcome the latest edition of *Stedman's*.

Preparations and Appliances

SOME USEFUL OPHTHALMIC SULPHONAMIDE PREPARATIONS

Dr. I. LLOYD JOHNSTONE (Worcester) writes:

Considerable attention has been given to the subject of local application of sulphonamides in ophthalmology. The early idea that this class of therapeutic agent was without effect when topically administered is no longer tenable. Without going into a review of the literature reference may be made to the work of Robson and Scott (1942), using sulphacetamide on experimentally produced corneal ulcers, and to an earlier clinical study of hypopyon ulcer effectively treated with sulphapyridine or sulphanilamide powder, or with soluseptasine as drops or by subconjunctival injection (Johnstone, 1941).

A need has been felt for a vehicle for these drugs which would keep them in contact with the diseased tissues in sufficient concentration and yet not insulate them. Such vehicles have been found, but, unfortunately, are in short supply. Messrs. May and Baker have made a sulphathiazole ointment (10%) in a soft wax base, and Messrs. Boots (Nottingham) an ointment of sulphacetamide (10%) in a water-miscible base of the appearance and texture of a cold cream. Both of these products are proving useful in various types of blepharitis, from acute abscess of the lid to the extremely chronic blepharitis with slight redness, itching, and scaliness of the lid margins. A case of dermatitis of the face from constant bathing with tears in a child with phlyctenular keratoconjunctivitis cleared up quickly with the sulphathiazole (thiazamide) ointment after being resistant to other forms of treatment.

Burns of the lids can be treated with the sulphacetamide cream, while burns involving the globe need an oily emulsion of the same drug. Unemul (Universal Emulsifiers Ltd.) has been used as an emulsifier, but there is difficulty in getting a stable emulsion unless a homogenizer is employed. A useful prescription is: sulphacetamide solution (from a 30% ampoule) 10%, water 25%, glycerin 30%, unemul 5%, cod-liver oil to 100%. Atropine sulphate (1%) must be added when the cornea is involved.

The dramatic effect of sulphapyridine in ophthalmia neonatorum will bear emphasis here. One-eighth of a tablet given with or after each feed will clear the condition in 48 hours. The treatment should be continued for a further 24 hours after apparent clinical cure. If this treatment is started early there should be no need to send a case to hospital. Local treatment of the eyes is reduced to a minimum. While discharge lasts it should be gently bathed away with cotton-wool pledgets soaked in warm saline. This should be repeated just often enough to prevent the lids from sticking. A drop of liquid paraffin or of 5% argyrol may be instilled each time, but so effective is the sulphapyridine that the drops can generally be omitted except as a memorial tribute to the past.

MOUTH GAG FOR LARYNGOSCOPY

Surgeon Commander H. PARRY-PRICE (Banbury, Oxon) writes:

I enclose an illustration of a mouth gag that has been made at my suggestion by Messrs. A. Charles King as an aid to direct laryngoscopy. Some patients have awkward gaps in the upper front teeth, and some difficulty may be experienced when passing a laryngoscope for direct-vision intubation. There is a gutter into which the teeth fit, and the spatula-like end controls the tongue. I find that with a preliminary spray of 2% percaine, followed by pentothal intravenously, it is perfectly easy to insert this prop and pass the tracheal tube.

NERVE REGENERATION

In addition to its intrinsic interest, the subject of nerve regeneration becomes increasingly important in time of war, and it is good to know that British workers are to the fore in attempts to solve the numerous theoretical and practical problems that arise in connexion with it. There is an extensive literature on the subject, as many as 928 papers being collected by Rossi and Gestaldi[1] up to 1934. Most of these lay emphasis on regeneration from the point of view of histology or function, but few studies have combined the two. In a recent review Young[2] has pointed out that the functional recovery of a regenerated nerve becomes complete only when the fibres are of a certain diameter and state of medullation, and can carry impulses of appropriate frequency and velocity. On this premise Holmes and Young[3] put forward six factors which may affect the success of secondary nerve sutures: (1) The first is the power of the central stump to send out new fibres. They find that this power is not affected when the axons are cut twice, either within a few days or nearly a year after the original injury. (2) The second is the power of the stumps to unite. This depends upon the outgrowth of Schwann cells from the peripheral stump. This outgrowth is at a maximum about two to three weeks after section of the nerve. There is evidence that union made after this interval is somewhat more successful than after primary suture. From about 100 days onwards the power of union declines, and long delays of union are less likely to succeed than primary suture. (3) The total diameter of the peripheral stump shrinks in the later stages of degeneration, sometimes by as much as a half. This fact makes a good suture difficult to effect and militates against the successful re-entry of fibres into the peripheral stump. (4) The shrinkage of the lumen of the Schwann tubes results in fewer fibres entering each one, and this in turn diminishes the chance of successful re-connexion. (5) After delayed suture, medullation is delayed in the peripheral stump and the fibres remain of small diameter for much longer than after primary suture. (6) The factor of re-innervation of end-organs is of great importance. Holmes and Young conclude that the process of the union of stumps and the regeneration of a new functionally efficient stretch of nerve are less satisfactory after the longer period of degeneration. Postponement of suture for one or two months does not prejudice the chances of recovery and may even improve them. Longer delays, especially those greater than six months, bring about conditions which are likely at least to retard recovery and may permanently prevent it.

Weddell[4] has correlated both the macroscopical and microscopical appearance of regenerating nerve fibres with the diminution of the area of sensory loss following interruption of nerve in the rabbit's ear. He finds that nerve fibres first advance along the original main nerve fasciculi. The first fasciculi to be re-innervated are those lying in closest proximity to normal nerve trunks. He has also found that cutaneous nerve bundles close to the larger blood vessels are more rapidly re-innervated than those further away. This, it should be emphasized, is distinct from the extension of adjacent normal fibres which also occurs towards the area of sensory loss. When the nerve trunks have become re-innervated the fibres pursue a tortuous course through the cutaneous plexus towards the skin surface. The finest visible endings of the nerve fibres are associated with Schwann cell pathways, which retain the pattern of the cutaneous plexus in the normal ear. On no occasion in the rabbit's ear has the tip of a regenerating nerve fibre in the cutaneous nerve plexus been seen pursuing a course independently of a Schwann band.

In a recent publication Weddell[5] observed that cutaneous sensory spots are each innervated by multiple nerve fibres. He suggests, therefore, that during the course of regeneration these will arrive at each separate spot at different times because they approach it from different directions, and the ultimate courses followed by the individual fibres will necessarily be of different lengths. Thus there will be a phase during regeneration in which each sensory spot is innervated by a single fibre instead of by multiple fibres. Such a stage in regeneration has now been found to occur, and hence the physiological findings of Trotter and Davies[6] are seen to have an anatomical basis—that is, if the process of regeneration of cutaneous nerve fibres in the ear of the rabbit can be assumed to be similar to that in man. The more rapid regeneration of nerve fibres along blood vessels is also in accord with the observations of Trotter and Davies, who observed that vasomotor control returned more rapidly than skin sensation. These phenomena evidently play some part in the process of diminution of areas of sensory loss which are observed clinically to take place from the periphery towards the centre of a degenerated area rather than from the centre outwards. In contrast with this mode of innervation the return of skin sensibility in regions not surrounded by areas innervated with normal nerves, such as the digits, is by an advancing wave of sensory recovery along the line of the cutaneous nerves supplying the skin. A similar phenomenon occurs in the rabbit's ear after complete denervation. The more rapid regeneration of cutaneous nerve fibres in the neighbourhood of blood vessels may serve to explain the bridges of cutaneous sensibility which are commonly found, in man, to cross an area of sensory loss during the course of regeneration from the proximal stump of the divided nerve.

The process of nerve regeneration throughout an area of skin involves first the rapid regeneration of nerve fibres along the main subcutaneous nerve trunks, and it is only at a later date that fibres extend from these trunks towards the skin by way of cutaneous nerve plexuses. In other words, regenerating nerve fibres ramify in the subcutaneous tissues some time before they give extensions to the skin itself. This is important from the point of view of nociceptive sensory tests which are used to determine the progress of sensory recovery. For instance, it has been found in clinical cases that " deep pricks " (2 to 3 mm. deep) will arouse pain in an area which is still anaesthetic to lighter pricks (1/2 to 1 mm. deep). This furnishes an explanation for the statement that one of the earliest indications of recovery of skin sensibility is pain caused by pinching the skin, for this manipulation necessarily includes the subcutaneous tissues. The importance of using standard instruments, which will give approximately constant stimuli from day to day in the same patient, cannot be overemphasized if a true picture of the course of sensory recovery (nociceptive) is to be obtained.

The work reviewed above has demonstrated the process of peripheral nerve regeneration in detail and has accounted in some measure for the clinical observations made on functional recovery. After complete division of a nerve early suture is important. In cases of incomplete division or neurapraxia (Seddon[7]), a most careful assessment of the damage done is essential before operative intervention is decided upon. To this end Guttman[8] has shown the value of the thermoregulatory sweating test, which gives a clear indication of the amount of autonomic damage in the cutaneous nerve. More recently Weddell, Feinstein, and Pattle[9] have shown that an accurate assessment of the injury to a peripheral nerve supplying a voluntary muscle can be made by electromyography. It is to be hoped that by combining these two procedures with a clinical examination the treatment and prognosis of peripheral nerve injuries will advance considerably.

To complete the picture of work in progress on nerve regeneration we will refer briefly to the less familiar problem of fibres in the central nervous system—a matter recently investigated by Le Gros Clark.[10] In 1910 Tello[11] implanted fragments of peripheral nerves in the brain. He claimed that regenerating fibres were seen in the graft, and in some sections could be seen penetrating the perineurium from the tissues of the host brain. Tello concluded that the Schwann cells were a source of a specific neurotropic substance which attracted fibres from cerebral neurones to grow towards them. Le Gros Clark, on the other hand, found a few regenerating fibres within his implanted graft in only 3 out of 13 experimental animals. In two cases regenerating nerve fibres were traced to a fasciculus accompanying newly formed blood vessels which approached the graft from the tissues of the host brain. In one case regenerating fibres within the grafted nerve fragment appeared to have entered the latter from the tissues at the surface of the brain. In no instance could regenerating fibres be traced into continuity with the fibres of the host brain, though the possibility of such a derivation could not be excluded. In some experiments many fibres of the surrounding white matter were disposed in fasciculi orientated towards the graft. This appearance was due partly to traction in the host tissue by the graft and partly to the dislocation of pre-existing fibres by a cellular infiltration. In two experiments spinal ganglia grafted into the brain showed great regenerative activity. Many fibres were found to penetrate into a zone of cellular infiltration separating the graft from the tissues of the host brain. However, no regenerating fibres from the host brain were found to extend into this zone towards the graft. It is concluded from these careful and detailed observations that the intrinsic fibres of the host brain have little if any regenerative capacity compared with peripheral nerves.

Sugar and Gerard[12] reported evidence of regeneration after section of the spinal cord in foetal and newborn rats. However, it is well recognized that the central nervous system of the newborn rat is very immature, and the postoperative growth of nerve fibres may well have been due to the developmental outgrowth of axons which would be proceeding normally at this time. These authors also cut through the spinal cord in young rats aged 3 to 5 weeks and in some cases reported regeneration across the scar. But, as is pointed out by Le Gros Clark, the anatomical evidence for this is not easy to assess; the consistency of the white matter of the central nervous system makes it difficult to produce clean lesions experimentally, and the fibres which appear to cross the scar at the site of lesion may be the frayed ends of the pre-existing fibre bundles pulled out of their normal position and left overlying the line of the knife cut. In addition to this the central nervous system of young rats even a few weeks old is relatively immature. Mitoses in the spinal cord reach their height in white rats about the 7th day after birth. It seems probable, therefore, that axons within the central nervous system do not regenerate once they are mature. It is also clear that the explanation for this is not to be sought in the absence of Schwann cells in the central nervous system but in other factors. Tower[13] has lately shown that the anterior horn cells in the spinal cord, when avulsed, can send out new axons along paths devoid of Schwann cells. There seems to be some factor related to all peripheral nerves which is absent in the intrinsic neurons of the central nervous system.

RESPONSIBILITY OF A PSYCHOPATH

The shortcomings of the "rules in M'Naghten's case" were again demonstrated in a recent trial for murder at the Old Bailey (Rex *v.* Lees-Smith). The defence alleged that the accused's act had been due to mental deficiency. Lengthy medical evidence was given concerning a number of laboratory tests which were applied to the prisoner. The witnesses found, in short, that he suffered from a congenital constitutional defect of development, manifesting itself as emotional immaturity, poor physique, and minor abnormalities of the central nervous system. He did not necessarily suffer from epilepsy, and in their opinion he suffered rather from psychopathic personality. They gave evidence that when his blood sugar was low and he overbreathed a change occurred in his brain whereby his judgment was impaired and his full perception of events was distorted. Before committing the crime of matricide he had drunk four pints of beer. A similar quantity given in the laboratory had the effect of lowering his blood sugar and aggravating his abnormality. The medical witnesses concluded, in terms of the M'Naghten rules, that when he killed his mother he knew what he was doing and that it was wrong, but his brain was functioning abnormally so that he was unable fully to appreciate the nature of his act.

The learned judge explained clearly to the jury the meaning of the M'Naghten rules, but in spite of his direction they found the prisoner guilty but insane. Everyone concerned with the case realized that the prisoner would almost certainly have been reprieved on the advice of the Home Secretary. The defect of the M'Naghten rules, which are now just 100 years old, is that they do not provide for the criminal who knows what he is doing and knows that it is illegal but, owing to a diseased or defective mind, cannot restrain himself from doing it. Many murderers have in fact been hanged in spite of strong evidence that their mental state had deprived them of self-restraint, and perhaps as many have been found guilty but insane in face of the M'Naghten rules. These rules were laid down by the common-law judges in 1843, and knowledge of human psychology has much advanced in the last hundred years. In 1924 Lord Darling introduced into the House of Lords a Bill to provide for the defence of "irresistible impulse," but it was opposed by several Law Lords and its mover withdrew it. The general feeling among lawyers seems to be that many criminals who richly deserve death would be able to persuade a jury that they had acted under an irresistible impulse. Persons who feel in this way perhaps underrate the capacity of juries to assess the medical evidence wisely and to reject a plea of this kind if the accused does not clearly show that his mental abnormality had robbed him of responsibility. They may also forget that the consequence of such a finding would not be acquittal but detention as a criminal lunatic. In the 1924 debate Lord Haldane said he had never heard of the M'Naghten rules embarrassing any judge when justice required an acquittal, and that there need be no fear that anybody who had acted under an impulse he could not resist was likely to be hanged. This *Journal*, commenting on the matter at the time,[1] said there were surely objections to a procedure by which prisoners are sentenced to death when, as Lord Sumner observed, the exercise of the prerogative of mercy is as certain as that the sun will rise the next day. The same comment is equally applicable to the present case. The law contains too many archaisms of this kind, and in too many important respects has fallen out of touch with reality. Doubtless this is an important factor in the ominous shift of power from the courts to the administrative departments which has marked the last two decades.

THE CONTAMINATED INJECTION

In 1928 a doctor in Bundaberg, Australia, used diphtheria prophylactic from a rubber-capped bottle of toxin-antitoxin which contained no antiseptic. Each time he wanted some more prophylactic he plunged the syringe needle through the rubber cap and took the required amount from what was left in the bottle. The material thus became contaminated with successive use, and of 21 children who were given injections of prophylactic on one day, 12 died of staphylococcal toxaemia caused by staphylococci which had been accidentally introduced into the bottle and had grown there. Bottles containing remnants of the same batch of prophylactic were then obtained from 33 doctors, and the fluid in 10 of these bottles was found to have become contaminated during use. Inadequate cleansing of the cap, non-sterile needles, or germ-laden air were suggested as possible causes. Every doctor in his daily work uses bottles containing several doses of prophylactic, or local anaesthetic, etc. To withdraw fluid through a rubber cap he must relieve the "vacuum" caused by the previous withdrawals; he therefore injects air with his syringe. The Australian Royal Commission, in its report on the fatalities at Bundaberg in 1928, described some experiments with these multiple-dose bottles. Sterile broth was put into sterile rubber-capped bottles, and a quantity of atmospheric air was forced through the cap with a sterile syringe. When this was done in a quiet room there was no contamination of the broth in the bottles, but when it was done in a dusty room with a ventilating fan running, the broth in 6 out of 11 bottles was found to contain bacteria. Air from a dusty room was next blown into bottles containing broth and 0.5% of phenol, but none of the broth showed any bacterial growth. It seems reasonably safe, therefore, to blow ordinary air into material which contains antiseptic in proper amount. Almost all medicaments in rubber-capped bottles have some antiseptic, but this is not enough to kill any spores that may be introduced through faulty technique. To make the procedure as safe as possible—alike for fluids with little antiseptic or none, and in unusually dust-laden air—some simple method might be devised for filling the syringe with sterile air. The sterile syringe needle might be buried in a tightly rolled sterile plug, or pushed through a rubber diaphragm of a sterile glass tube with a sterile stopper at the other end. This may seem a cumbersome procedure, but may be well worth remembering in special circumstances: the Australian doctors in their ordinary daily work contaminated 30% of the bottles of prophylactic.

VITAMIN C AND CARBOHYDRATE METABOLISM

The relation of vitamin C to carbohydrate metabolism has often been investigated in the past few years. The reports so far are rather contradictory, though the majority of them suggest some sort of a relation. The method of investigation usually employed was a measurement of either the fasting blood-sugar level or the sugar-tolerance curve after administration of the vitamin. Most workers reported a fall of blood sugar; some failed to notice any change, while a few even observed a rise. A change of blood-sugar level resulting from the administration of the vitamin can hardly be taken as conclusive evidence of the latter's relation to carbohydrate metabolism, for the change might be the result of a lowering of renal threshold, or be due to the influence of some other mechanism following administration of the vitamin.

Recently from the Bispeljerg Hospital, Copenhagen, have come two more reports indicating a lowering of blood sugar after administration of vitamin C. The first work[1] involved a measurement, after intravenous injections of vitamin C, of the change in fasting blood sugar in hospital patients with normal blood-sugar levels. A control was obtained by giving the same patients injections of plain water. Vitamin C caused a fall of blood sugar in the majority of the cases examined. The magnitude of the lowering, however, bore no relation to the initial vitamin C content of the blood, nor did it correspond with the variation in the concentration of the vitamin in the blood after injection. As pointed out above, these observations by themselves are insufficient proof that the vitamin is directly related to carbohydrate metabolism. The second paper[2] refers to glucose-tolerance tests on patients at varying levels of vitamin C nutrition. Some subjects whose blood vitamin C was very low showed a diabetic type of glucose-tolerance curve with an abnormally high maximum, which was amenable to treatment with the vitamin. These subjects were distinguishable from true diabetics, whose sugar-tolerance curves were not much altered by treatment with the vitamin, though there was sometimes a slight lowering of the maxima. Hyperglycaemia not uncommonly occurs in infectious diseases, and the suggestion is thrown out that it may be caused by the deficiency of vitamin C which often accompanies infection. These observations still need confirmation in view of the small number of cases studied, and their interpretation should be viewed with reserve. Certainly it would be unwarranted to assume that ascorbic-acid deficiency is the sole cause of abnormal sugar tolerance in all cases of "pseudo-diabetes."

NEW LIGHT ON PERIARTERITIS NODOSA

A. R. Rich of the Johns Hopkins Hospital, Baltimore, whose studies of allergy are well known, has produced evidence[3] that periarteritis nodosa may be a manifestation of the anaphylactic type of hypersensitivity. In the first of the cases which led him to this conclusion death had followed shortly after an attack of serum sickness. The opportunity to study the morbid histology of this condition has rarely occurred in the past: when serum was the only form of specific treatment available for pneumonia and meningitis, patients either died before serum sickness was due to develop, or recovered. Sulphonamide treatment now prolongs the lives of desperate cases in which serum has also been used, and serum sickness may have occurred before death. In several such cases vascular lesions indistinguishable from those of periarteritis nodosa were found in various organs post mortem. The naked-eye changes associated with this disease are not mentioned as having been observed, but the microscopical appearances of necrosis of the arterial wall with dense leucocytic infiltration in and around it are characteristic: haemorrhage around the vessel and the presence of eosinophils were sometimes observed and sometimes not. Of the 6 cases in which serum had been given, 5 had also had sulphonamides, but there were good reasons in 2 of them for regarding the rash and other manifestations as due to the serum and not to the drug, while in the sixth case serum alone could have been concerned. But the new argument does not stop here, because two other cases are described in which the same arterial lesions were found, and these patients had been treated with sulphonamides only: one had a typical drug fever with urticaria before death, the other a condition regarded as a febrile reaction to the drug but with no local manifestation other than a conjunctivitis. It therefore appears that sensitization to a sulphonamide compound may result in a vascular reaction of the same nature—that, in fact, serum sickness and drug fever, the clinical manifestations of which are certainly alike, have the same hitherto unrecognized basis. It is suggested that the drug may become linked with one of the plasma proteins, thus acting as a haptene, the body becoming sensitized to this compound; there is, indeed, evidence that this can occur. None of these patients exhibited any signs of periarteritis nodosa before the final illness, and successive biopsies were made in one case which fixed the time of development of the arterial lesions as coinciding with the clinical reaction of hypersensitivity.

---

[1] Sylvest, O., *Acta med. scand.*, 1942, **110**, 183.
[2] Secher, K., ibid., p. 255.
[3] *Johns Hopk. Hosp. Bull.*, 1942, **71**, 123, 375.

Whether these findings can wholly bear the rather startling interpretation placed on them depends on whether the vascular lesion described can be considered truly specific. It is not inconceivable that necrotic and inflammatory arterial changes of this nature can arise in more than one way. This question brings strongly to mind the prolonged controversy which has been fought over the identity of the natural rheumatic lesion with those produced by the German school of allergists by means of foreign proteins to which the body had been sensitized. How far histological criteria can be depended upon in deciding aetiology is indeed a much broader question, on which there will be no general agreement. But Rich has performed a valuable service in opening a new line of investigation of an obscure disease. Any case of periarteritis nodosa should now be studied from this standpoint, and when the diagnosis has been made during life every effort should be made to determine whether a state of hypersensitivity exists to any identifiable agent.

INQUIRY INTO GROWING INCIDENCE OF JAUNDICE

The Medical Research Council, acting on a request from the Ministry of Health and in consultation with the War Office, has undertaken a special investigation into the causes of the present increased incidence of different forms of jaundice. The scheme is being generally directed by a committee of the Council under the chairmanship of Prof. L. J. Witts and with Dr. A. M. McFarlan as secretary. The headquarters of the investigation have been established in the Department of Pathology, University of Cambridge, by arrangement with Prof. H. R. Dean. The inquiries will be mainly made within a convenient radius of that centre, and cases occurring in military units as well as among the civilian population will be investigated. The team at Cambridge consists of five whole-time workers. The services of Dr. F. O. MacCallum as senior bacteriologist have been lent by the Wellcome Research Institution; Major Clifford Wilson (physician) and Captain J. A. R. Miles (clinical pathologist) have been seconded from the R.A.M.C.; and Dr. A. M. McFarlan (epidemiologist) and Dr. M. R. Pollock (assistant bacteriologist) have been attached from the Emergency Public Health Laboratory Service. In addition, Prof. S. P. Bedson is acting as general adviser on behalf of the committee. Prof. G. Hadfield has agreed to undertake the examination of histological material, and Prof. M. E. Delafield to collate epidemiological reports from various sources.

A TRACT FOR THE TIMES

The myth of the "machine man" dies hard. In spite of so much that has been discovered on the subject since the great industrial push following Dunkirk, the idea still persists among leaders of production drives and other people that the longer the hours worked the greater will be the output and that it will all be at the same qualitative level. Dr. H. M. Vernon has therefore done another good service by composing a tract entitled *Hours of Work and their Influence on Health and Efficiency*,[1] in which he assembles evidence to show the influence of working periods on the capacity of the worker. The evidence includes the reports of the Health of Munition Workers Committee in the last war, as well as the peacetime investigations of the Industrial Health Research Board, but mostly it consists of the results of inquiries on the industrial front since 1940. All this evidence points conclusively to the fact that excessive hours result in minor sickness, increased accident-proneness, and casual absence, and also in graver injuries to the worker. Readers of the *Journal* will recall the paper published less than a year ago (July 18, 1942) by Laidlaw and Macfarlane, based on observations particularly among women workers in Glasgow, which suggested that hours of work played an important part in the causation of pulmonary tuberculosis. Dr. Vernon is not content to rely solely on statistical argument, abundant as that is, but he points out fundamental psychological causes whereby the human factor will always in the end confound Pharaoh. There is, he says, an unconscious adjustment on the part of the worker to the hours he works. When the hours are long he gets into the habit of working at a slower pace. When these excessive hours are suddenly shortened the pace of the work for a time continues much as before, and production falls almost in direct proportion to the shortening of the hours; but presently, owing to the increase of vigour as a result of lighter work, the worker gradually and unconsciously speeds up—a process which continues for three or four months, and then attains equilibrium at a level substantially higher than that observed when longer hours were worked. Another factor in the present situation sometimes overlooked is that for women workers the toil does not usually cease when they leave the factory; shopping (never so exhausting as now) and household duties lay further exactions upon them. Dr. Vernon does not disguise his dislike of the regulation that women, unless they do 55 hours' work a week on business premises, must undertake fireguard duty. He suggests certain minimum hours for women and for girls and youths, while as for men he says that anything in excess of a 60-hour working week will bring no increase of production, and if the work is heavy, shorter hours than these are advisable.

The next session of the General Medical Council will open on Tuesday, May 24, at 2 o'clock, when the President, Mr. Herbert Lightfoot Eason, will take the chair.

THE ARMY BLOOD TRANSFUSION SERVICE

The Army Blood Transfusion Service is unique. No other army, Allied or Axis, has a distinct transfusion service with its own source of supply and its specially trained mobile resuscitation units. The headquarters of this Service were established six months before the war, and the plasma-drying plant, which was presented to it by the Silver Thimble Fund of the Women of India, was erected in 1941.

Scope of the Service

The Service now operates from Reading to Penzance in some 850 different centres. It has a staff of about 350, of whom more than three-quarters are women (either V.A.D.s or A.T.S.).

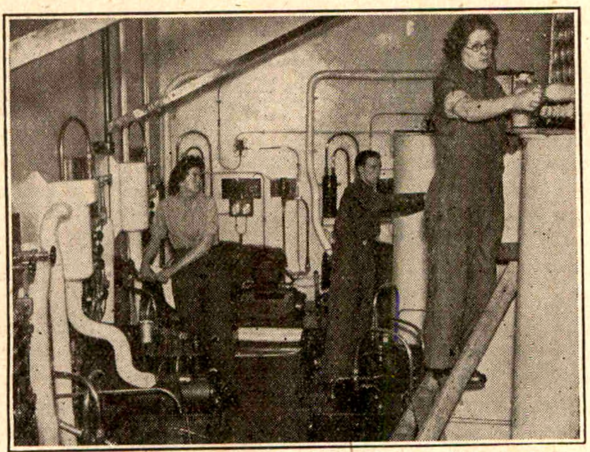

FIG. 1.—Part of the plasma and serum drying plant of the Army Blood Transfusion Service, showing the refrigerating and vacuum pumps. On the right one of the primary desiccators is being unloaded of its dried plasma.

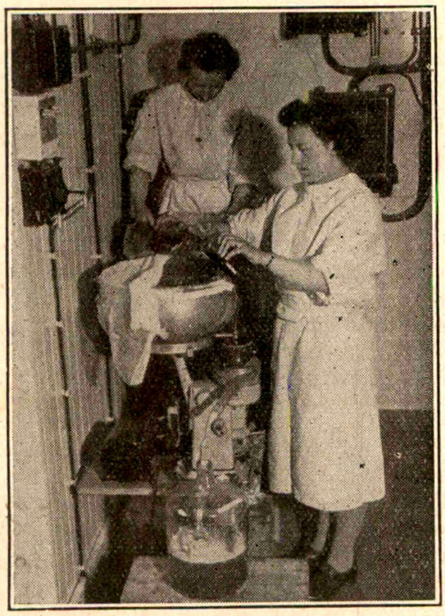

FIG. 2.—Pooling and separation of the plasma and red cells. The nearest operator is pouring donated blood from the standard M.R.C. bottles into the container through the muslin gauze. The Alfa-Laval separator has two outlets—one for plasma (seen nearest the camera and filling the Winchester) and the other for the red cells on the other side.

The original technical staff was drawn largely from the laboratory staff of the Royal College of Surgeons and the Middlesex Hospital. The Service supplies with transfusion fluids and equipment the whole British Army over-seas, from Iceland to the Cape of Good Hope and from Tunis to Burma. It supplies the basic requirements of the Forces at home and the civilian population in a Ministry of Health Region. It trains and equips units for service over-seas, and trains all ranks of the R.A.M.C. in resuscitation work. Since the beginning of the war blood has been taken from more than a quarter of a million donors. The 20 members of the staff of the Donor Registration and Publicity Department have to keep up to date the records of the three to four thousand donors who are bled each week. The bleeding is done by 15 mobile, self-contained, fully equipped teams, each consisting of a medical officer, 4 V.A.D.s, 2 A.T.S. drivers, and an A.T.S. orderly. The teams are detached, and quartered in the large towns, from which they "bleed" the surrounding area for a distance of 25 to 30 miles. Since 1939 two women doctors have between them bled more than 35,000 donors.

Transport of Transfusion Fluids

Whole blood is transported to any theatre of war within air distance of England, and in order to reduce shaking in transit the bottles are, by means of a special apparatus, filled to the top with glucose solution. Large insulated boxes are, by means of ice-inserts, kept at a temperature of 4° C. for a period of 8 hours. But most of the blood taken by the Service is separated, clarified, and filtered to make fluid plasma, which is sent out as such for military use at home and in temperate climates. That sent to the Army in tropical and subtropical regions is dried, and some twelve to fourteen hundred bottles come off the drying plant each week. Distilled water for reconstitution is sent with each bottle of dried plasma. Already some 56,000 pints of fluid plasma have been exported, and getting on for

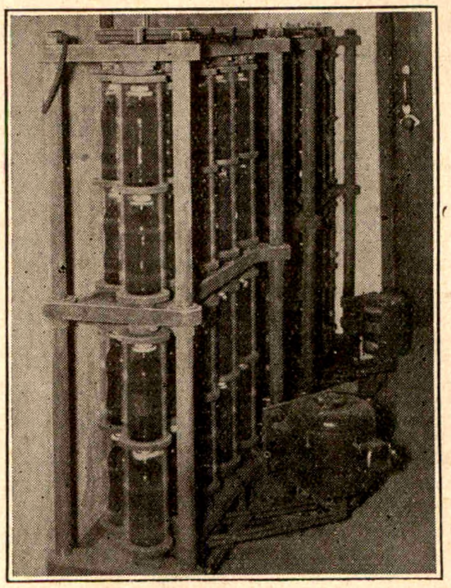

FIG. 3.—Bottles of liquid plasma in the spinning machine. The bottles in the photograph are actually spinning round at 1,000 revolutions per minute and stay so for 2½ hours at a temperature of −17° C. The effect is to form a vortex in each bottle, and when removed from the spinner each bottle contains what is in effect a tube of frozen plasma. Reconstitution with the appropriate quantity of sterile distilled water is complete in under 60 seconds.

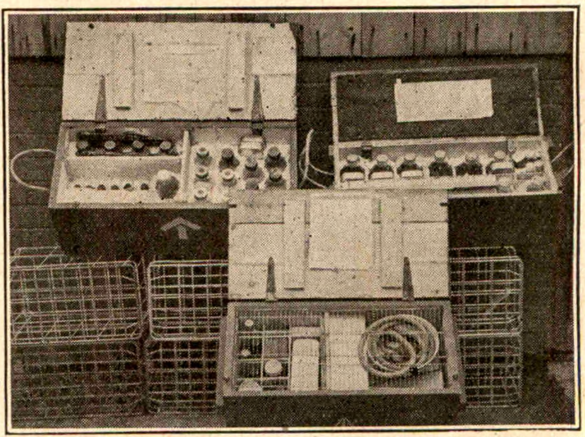

FIG. 4.—Three of the special boxes of the Army Blood Transfusion Service. *Bottom:* The field transfusion box—instruments, dressings, morphine, and drugs, tourniquets, etc., for the use of the medical staff. *Top left:* The field pattern box, containing sets for giving and taking blood; dried plasma and sterile distilled water, and glucose-saline. *Top right:* The specially adapted air-borne box containing instruments, dressings, drugs, wet plasma and dried plasma, and giving sets.

50,000 of dried plasma. Apparatus for administration assembled at the home depot is sent with all transfusion fluids, the apparatus being packed in tins, sterilized and ready for immediate use. The Service has also devised and issued special boxes of equipment to meet the transfusion needs of military hospitals, field ambulances, and troopships, as well as complete apparatus for full resuscitation by mobile field transfusion units and by airborne medical units. Another of the jobs of the depot in the South-West of England is the preparation of crystalloid solutions (glucose and saline) for all units at home and over-seas which are unable to prepare these themselves. The Service also supplies dried grouping serum.

Oversea Units

In every theatre of war over-seas the home service is linked to a base transfusion unit, which obtains from the headquarters at home the supplies required on the spot. These base transfusion units are also equipped for the production of crystalloid solutions, for the assembly of apparatus, for servicing and repair of refrigerators, and for obtaining blood locally. For example, the M.E.F. base unit has been able to maintain a service of whole blood to the 8th Army to supplement the dried plasma sent from home. Serviced by the base unit are mobile field transfusion units, fully equipped for the performance of resuscitation in the field. In North Africa these units have operated mainly in co-operation with field surgical units to form complete advance surgical centres with field ambulances, field dressing stations, and casualty clearing stations.

It has been said that the work of the doctor serving with the armed Forces has in this war been facilitated by three main innovations: (1) intravenous anaesthesia; (2) local application of sulphonamides to wounds; and (3) transfusion of blood and of plasma. Blood transfusion was, of course, used in the last war, but refrigeration and the use of fluid and dried plasma have revolutionized the application of blood transfusion in the field. That the fullest scope has been found for these new blood-transfusion techniques is due to the energy, wisdom, and brilliant organizing abilities of those who have built up this magnificent Service.

The photographs reproduced were taken by Mr. Norman K. Harrison of the "Topical" Press Agency Ltd.

CANCER RESEARCH

WORK IN PROGRESS

The annual meeting of governors of the Imperial Cancer Research Fund was held at the Royal College of Surgeons on April 29. The annual report, which was presented by Prof. H. R. Dean, chairman of the Council, described the continued work in various branches of research which has occupied the seven members of the scientific staff and the three visiting research workers during the last and previous years. The financial statement, presented by the treasurer, Sir Holburt Waring, showed the total receipts of the Fund during the last financial year to amount to £16,319, an increase of £1,561 as compared with the previous year. On the motion of Sir Hugh Lett, Viscount Halifax was re-elected president, and on the motion of Sir Alfred Webb-Johnson, Sir Holburt Waring was re-elected treasurer. Prof. H. M. Turnbull and Sir Hugh Lett were elected as "elected members" of Council for a period of three years, and the four "appointed members"—namely, Profs. H. R. Dean, H. W. Florey, C. A. Lovatt Evans, and John Beattie—were reappointed, also for three years.

In his report of the scientific work of the Fund[1] the director, Dr. W. E. Gye, F.R.S., observes that circumstances have been unfavourable to some kinds of research work—for example, to the study of viruses, for which large numbers of rabbits and fowls are needed. As small animals, such as mice and rats, are more easily reared and fed, work has been directed largely to investigating mammary cancer in mice, chemical carcinogenesis, the action of the hormones on the pituitary and the prostate, and to chemotherapy.

Carcinogenesis

Mr. H. G. Crabtree, M.Sc., has continued his work on the mode of action of chemical carcinogens, especially 3:4-benzpyrene. He has already shown that a series of halogen compounds can retard the development of skin tumours induced by pure chemical substances. The power to check such formation was parallel with the power to check glycolysis. Such compounds were also found to affect other chemical cell mechanisms, in particular those involving the sulphydryl group (—SH). Sulphur metabolism is now believed to play a part in the artificial induction of cancer. Apparently the general growth-inhibiting properties of many carcinogenic and non-carcinogenic hydrocarbons are related to the depletion of sulphur-containing amino-acids which co-operate in their elimination. It was therefore decided to make further investigations into the effect of sulphur metabolism on tumour induction. A brief description is given of experiments on the inhibiting effect of bromobenzene on skin tumours induced in mice by painting with benzpyrene. In one experiment an application of the former to the same area of skin painted by the latter increased the induction time for papilloma formation by about 50%. The organism detoxicates bromobenzene by combination with cysteine and subsequent elimination of the resulting mercapturate. From these and other experiments it is concluded that bromobenzene reacts with sulphydryl-containing tissue components. It appears that localized deficiency of sulphur is the determining factor in inhibition of tumour induction. It is thought that sulphur metabolism is intimately concerned in chemical carcinogenesis.

Dr. B. D. Pullinger's work suggests that trauma has a slight stimulating action in the production of experimental tumours. Trauma alone is, however, not enough, and the intervention of a specific carcinogen is apparently also necessary. This has a bearing upon the rare human instances of association between trauma and tumour.

Hormones

Dr. E. Vasquez-Lopez is working on the reactions of the pituitary body to prolonged treatment with oestrogens, implanted subcutaneously. It is found that under the influence of oestradiol benzoate and diethyl-stilboestrol the pars intermedia—not the anterior lobe—of the hamster becomes enlarged. The cells of the intermedia multiply and invade the posterior lobe, this being regarded as an increase in degree and extension of a normal process. The report points out that the hypophysis-oestrogen relationship has always been referred to the anterior lobe, and that these experiments at least serve as a reminder that the pars intermedia is a pituitary component which is functionally active. Similar overgrowth of the pars intermedia has been found in rabbits treated with thyroxine.

Tissue Culture

Dr. R. J. Ludford and Miss Hilda Barlow have been studying tissue culture of spontaneous tumours or tumours induced experimentally, previous observations having been made largely on the cells of transplanted tumours. It is found that, in general, carcinomas grown *in vitro* form compact sheets of cells, thus resembling normal epithelium. The fibroblastic type of growth is followed by sarcomas. Cultures of primary sarcomas contain many wandering cells as well as the malignant cells. In contrast there were few wandering cells in cultures of mammary carcinomas. No difficulty was experienced in distinguishing the morphology of sarcoma cells from that of fibroblasts, but when mammary gland of pregnant mice and spontaneous mammary carcinomas of high-cancer-strain mice were grown together in culture it was not possible to distinguish which cell was which by examination of the nuclear structure.

Fibroblasts grow prolifically when cultured with spontaneous mammary carcinomas of high-cancer-strain mice. A similar phenomenon was observed when fibroblasts were grown with non-malignant epithelial cells (growing embryonic kidney). In contrast, sarcoma cultures were found to inhibit the growth of fibroblasts. It is concluded that growing epithelial cells stimulate the growth of fibroblasts, and that the biological significance of this may be the need of epithelial cells *en masse* to have connective-tissue support.

In times like these it is much more difficult to carry on the kind of long-term research work which is needed in cancer than to turn attention to *ad hoc* war problems, and the profession will be glad to know that in spite of all these difficulties the Fund is continuing to give its valuable services to research; and medical men, too, will bear in mind that this work cannot be carried out without money.

---

[1] Fortieth Annual Report, 1942-1943, of the Imperial Cancer Research Fund, April, 1943.

Correspondence

Is Anaemia Prevalent?

Sir,—The absence of one of us on holiday has delayed this reply to your interesting leader (April 10, p. 449). The writer of that leader is under the impression that we "argue that there has been a general lowering of haemoglobin values in the population." In fact we agree with him that the evidence existing does not at present warrant any such conclusion. Though the haemoglobin level in the groups examined—of children as well as women—for example, by Davidson in Edinburgh and by ourselves in or near London, is, we think, disquieting, yet we hoped we had stressed the limited nature of our material. For example, we examined no men, few school children, and women in one factory only, not "in factories," as stated in the *Journal*, and, to quote our own words, "our investigation covers only a few sample groups, and the incidence of anaemia may well vary widely."

We have no evidence that would warrant the suggestion made in your article that "10% of the female population" have a haemoglobin level below 80%, and we have no means of assessing the number, nor, in spite of the absence of information on the limits of normal for women and children, do we think that many clinicians would accept 80% as the lower limit of normal for women.

We are glad that part of our aim is accomplished, for interest has been aroused in the subject, and (*pace* your leader writer) two official bodies at least—the Ministry of Health and the Medical Research Council—have initiated widespread haemoglobin surveys.

Your leader writer thinks that our town and country groups of students may not have been comparable. Actually, the choice of students for the London or country hospital was made by the medical school authorities on an educational basis, and no selection, such as he suggests, occurred. We had hoped we had made this clear. We owe an apology to the two hospitals concerned. By an oversight certain articles in the nurses' diet, practically pure carbohydrate and fat, were omitted from our computation. In London we were able to get details of these, and they added 240 calories a day to the diet, and it is probable that an addition of the same order should be made to the country diet as given in our article. This was an error on our part, but does not invalidate our argument.

The aetiology of the existing anaemia certainly requires investigation, but that is too large a subject for discussion in this already overlong letter.—I am, etc.,

Royal Free Hospital, W.C.1. Lucy Wills.

The Constitutional Factor

Sir,—I was fascinated to read your leader on the constitutional factor (April 24, p. 510). Prof. Bauer's contention appears to be that particular defects in the chromosomes are reflected in particular diseases in later life, the latter arising from foci of diminished resistance pre-ordained by the defective genes. This concept appears to agree substantially with my own theories, which I have applied particularly to the strain diseases, by which I mean those chronic constitutional diseases of increasing incidence in recent decades, like peptic ulcers, chronic rheumatism, diabetes, hyperthyroidism, arteriosclerosis, etc. Bauer's main conception, to quote your leader, "is that the genes act directly on the effector organ"—i.e., the organ through which the disease is expressed—" or indirectly through either the endocrine system or the nervous system, which can themselves collaborate."

The view expressed in my book, *Disease and the Social System*, is that, at any rate in the strain diseases, the primary factor is an innately vulnerable nervous system. In other words, I believe in a neuropathic aetiology in conditions other than those considered to be neurological or psychological in nature. I believe that this broad neuropathic diathesis is more specifically expressed in different varieties of dysfunction in the autonomic and endocrine systems. The specific pattern of the individual's disease is determined by the particular defect in his autonomic–endocrine liaison. An important observation in relation to the foregoing theory is the frequency with which, given the innate neuropathic diathesis, different members of the same family will produce different types of autonomic endocrine morbidity. One sees so often within the *milieu* of one family different varieties of the strain diseases.

It must be admitted that in some of the commonly associated strain diseases endocrine factors are not obvious according to the current tenets of clinical observation. Duodenal ulcer and chronic articular rheumatism are often found together in the same family. But I firmly believe, for reasons which space precludes me quoting here but which I have adduced in my book, that the endocrine factor in such diseases is of immense importance as well as in the deteriorating "abiotrophic" conditions like paralysis agitans.

But above all, at any rate in the commoner chronic diseases, the neuropathic factor is of first importance. The theory of a growing vulnerability of the nervous system may appear at first sight crude. In the last fifty years of improved hygiene and sanitation the only infective conditions showing a steady increase are the fevers affecting the nervous system. Is not this, perhaps, taken together with the increase in psychopathological conditions, a fact and an omen of great significance?

Apropos your last paragraph, I feel that, with all respect to the public health authorities, the art of preventive medicine is only being born, that it is a form of clinical medicine, and that it can only be elucidated by individual physicians for the benefit of individual patients, because it must consist so essentially in developing the patient's self-knowledge of his own innate and particular defects.—I am, etc.,

Bath. A. Guirdham.

Direct Inguinal Hernia

Sir,—In the *Journal* of Feb. 11, 1939 (p. 263), Mr. W. G. Gill drew attention to a rare type of direct inguinal hernia and described three personal cases. I recently encountered a similar case at operation. Bearing in mind the apparent rarity of this condition, and being impressed by its very real existence as a variety of direct inguinal hernia, it seemed to be worth while to put the following on record.

The patient, a chief petty officer aged 46, presented himself for operation with a right-sided rupture of about 5 years' duration. He had first complained of a lump and of discomfort in the right groin following a strain while lifting a heavy weight when employed in a cordite factory. He consulted his doctor at the time and was fitted with a truss, which appeared to control the rupture adequately.

On examination there was a visible and palpable impulse on coughing and an appreciable enlargement of the right external ring. A pre-operative diagnosis of right inguinal hernia was made, which was thought to be most probably of the direct type. At operation a small hernial sac was encountered lying medial to the inferior epigastric vessels. It had a generous fatty covering almost amounting to an extraperitoneal lipoma, which had to be divided layer by layer before the sac could be completely displayed. (It closely resembled the typical femoral hernial sac.) It was about 1 in. long and had a narrow neck, which was found to be firmly engaged in a very obvious circular defect in the transversalis fascia. This had firm edges and would only admit the tip of the little finger. The opening was enlarged in order adequately to expose the neck of the sac, and on clearing its medial aspect the bladder was encountered and avoided. The neck was then ligated and the sac removed. The opening in the transversalis fascia was readily closed with interrupted sutures of No. 2 catgut. The cord was then replaced and no other repair of the posterior wall of the canal attempted.

He made an uninterrupted recovery, passing urine without difficulty from the beginning.

Although it is unreasonable to hazard a guess as to the causation of such a condition from the observation of a single case, my own feeling is that the sac develops as a direct sequel to an initial weakening of the transversalis fascia by a pro-peritoneal lipoma as in the epigastric type of hernia (as suggested by W. H. Ogilvie in Maingot's *Post-graduate Surgery*, 1937).

My thanks are due to Surgeon Captain H. F. Briggs, R.N., for permission to publish the notes of this case.—I am, etc.,

M. R. Ewing,
Surg. Lieut., R.N.V.R.

Treatment of Malignant Tertian Malaria

SIR,—The case of malignant tertian malaria recorded by Drs. W. L. Anderson and D. B. Bradshaw (April 24, p. 508) is of interest inasmuch as the man was apparently cured by quinine. The patient in the case recorded by Shute and myself in the *Lancet* (1942, **2**, 365) had, in point of fact, been taking regular doses of quinine, which suppressed the severe malarial symptoms without curing the disease, and it was not until quinine was discontinued that the diagnosis of malaria was possible.

In the case reported by Anderson and Bradshaw the small doses of quinine did not prevent the diagnosis of malignant tertian malaria being made, but it did suppress the severe clinical symptoms, and had quinine been stopped there is little doubt that these symptoms would have been much more severe. An important finding was the large number of gametocytes (crescents) present in the peripheral blood. This is evidence that the patient had been suffering from malaria for some considerable time, and that the quinine had failed to destroy the asexual parasites, because, had this been so, gametocytes could not have been so numerous. Mepacrine (atebrin) would have probably benefited the patient more than did the long-continued daily doses of quinine.

As regards the mepacrine treatment, when a severe case of malignant tertian is admitted to hospital it is the practice at Horton to treat the patient as follows: on the 1st day 0.6 g.; on the 2nd day 0.3 g.; on the 3rd and 4th days none; on the 5th, 6th, 7th, and 8th days 0.3 g. The reason for giving a reasonably large dose on the 1st day is that the parasites are subjected to drastic treatment, which will destroy most of the developing forms, either in the peripheral or internal circulation, particularly in the capillaries of the brain. The dose of 0.3 g. on the 2nd day will kill off most of the survivors of the previous day's treatment. The two-days rest followed by 0.3 g. for a further period of four days invariably cures the attack and possibly the disease as well.

Finally, a few small doses of plasmoquin 0.02 g. twice weekly for two or three weeks would have destroyed the sexual parasites (crescents) and so rendered the patient uninfective to anopheles mosquitoes.—I am, etc.,

Epsom. J. ELLIOT MURRAY, M.D.

The Calcium Intake in Pregnancy

SIR,—There seem to be three imperfections in the *Journal* for May 1. First, the "centrifuge tube for collection of leucocytes" described by Dr. M. A. Gohar (p. 542) is merely a copy of the tube introduced by Mindlin and Butler (*J. biol. Chem.*, 1938, **122**, 673) for separating the leucocyte-platelet layer of blood so that vitamin C may be estimated in it. Various workers have been using their method; we have been using tubes that contain about 3.5 ml. blood from which about 10 mg. of leucocyte-platelet layer are obtained, and the tubes are made by a laboratory glass-blower.

Secondly, your annotation on riboflavin and corneal vascularization (p. 545) seems to confuse the latter with circumcorneal injection. The two are obviously not synonymous. One connotes the formation of new vessels, the other the dilatation of existing vessels such as can be produced by rubbing the eyes. You say that the value of corneal vascularization as a sign of deficiency of riboflavin has recently been questioned in this country, quoting Scarborough. He confined his examination of the eye to circumcorneal injection, "but in no case was the slit-lamp used"; his observations therefore neither confirm nor refute the value of corneal vascularization as a sign of deficiency of riboflavin.

Thirdly, Dr. Robertson criticizes me (p. 550) for an alleged statement that "supplementary feeding of calcium . . . might prolong pregnancy and harden the foetal skull." My contribution to the meeting of the Scottish Group of the Nutrition Society was upon the evidence for nutritional deficiencies in pregnancy, and I was careful to state both sides of each question with which I dealt. Therefore, concerning deficiency of calcium in pregnancy, I spent some time on the well-known work on such deficiency, and on the other side included but one sentence upon possible dangers of calcium overdosage. My notes, I find, devoted 292 words to the work (which Dr. Robertson quotes) of Coons and the Toveruds, and on the other side only 15 words to the work of Abel, who observed (*Z. Ernähr.*, 1931, **1**, 366) that administration of a preparation of vitamin D prolonged the average duration of human pregnancies by about ten days, but who suggested that caution in the use of concentrates of vitamin D was necessary in case the bones of the infant's skull became too hard. I thought this work so unimportant that I omitted any reference to it in the written paper submitted for publication in the *Proceedings*. I have also stated in a letter to a colleague last March that I "completely agree with you in emphasizing the great value of a high calcium intake in pregnancy. However much chalk one ate one could not, I imagine, obtain Abel's results." I therefore consider that I anticipated the advice that Dr. Robertson now kindly gives me, in that I "stressed the well-established complications resulting from calcium deprivation rather than the unproven dangers of calcium overdosage."—I am, etc.,

Oxford. H. M. SINCLAIR.

Sulphaguanidine in Neonatal Gastro-enteritis

SIR,—Drs. C. Elaine Field and W. G. Wyllie (April 17, p. 486) say it is unfortunate that my clinical trial of sulphaguanidine in "infantile gastro-enteritis" was inadequately controlled, and apparently disagree with the statement in my paper (April 3, p. 410) that the greatly improved results achieved by its use did not justify this procedure. I would remind them that my paper was concerned only with epidemic gastro-enteritis in the newborn, which differs in some important respects from gastro-enteritis in older infants; also that controlled experiments involving serious risks can be justified only in experimental animals.

Research workers usually suspect the validity of inadequately controlled observations. Such a critical attitude is most necessary. I am not surprised, therefore, that my observations have failed to impress Drs. Field and Wyllie, as the value of sulphaguanidine was not proved in my series of cases by omitting it from the standard therapeutic regime in alternate cases. We all realize that clinical impressions, like inadequate controls, can be most misleading and are scientifically unsound, but I would assure my correspondents that all those with experience of neonatal gastro-enteritis who witnessed the investigation were so much impressed by the beneficial effect of sulphaguanidine that one would have been considered most inhuman to withhold it in any case.

My observations on sulphaguanidine therapy in neonatal gastro-enteritis were based on a relatively small series of cases, but the results were so promising that I thought it desirable to acquaint others, at this stage of the investigation, with its value in this disease, which causes so many deaths in maternity hospitals. I concluded my paper with the remark: "More experience with sulphaguanidine in neonatal gastro-enteritis is needed."

I was much interested in "the standardized plan of treatment" followed by Drs. Elaine Field, MacCarthy, and Wyllie in their careful study of gastro-enteritis in older infants (March 27, p. 371), but I was disappointed that they did not mention sulphaguanidine. I fully agree with their "further recommendations" (5–9) for prevention.—I am, etc.,

Edinburgh. J. L. HENDERSON.

Intolerance to Liver Extract in Pernicious Anaemia

SIR,—The importance of the article on intolerance to liver extract in pernicious anaemia (May 1, p. 539) is underlined by a patient of my own who died after an injection given on April 27. He was aged 83 and had been under treatment for pernicious anaemia for about five years. A year ago he suddenly became intolerant to his injection, and had one bad attack of dyspnoea and cyanosis and partial collapse relieved by adrenaline. After this there was a gap, during which ineffective attempts were made to get him to take sufficient liver extract by the mouth. Recently I decided to try again by injection, and instead of his usual dose of 5 c.cm. I gave a dose of 1 c.cm. Apart from slight skin irritation this was well tolerated, and four weeks later I gave a dose of 2 c.cm. In twenty minutes the patient was dead with acute respiratory failure, against which adrenaline and respiratory stimulants were useless. The article appeared four days too late.—I am, etc.,

Bristol. C. CHRISTOPHER MORGANS.

Treatment of Dysentery at Sea

SIR,—I have read with interest the letter of Flight Lieut. A. G. McManis and Major W. Gordon Rich on the treatment of dysentery at sea in your issue of Jan. 16. I fail to see, however, that treating dysentery on shore and at sea are so very different that injections of emetine hydrochloride have to be tried on the supposition that cases which do not clear up with ol. ric. and mist. bismuthi are due to amoebic infection.

In my experience there have always been a microscope and a few stains on board ship, and iodine and potassium iodide can be obtained from the dispensary for staining amoebae. Granted that cultures cannot be made, but fresh specimens of stools are easily obtained and stained. Bacillary dysentery can then be diagnosed on the typical cellular exudate found in this infection, and amoebic dysentery on the presence of the *Entamoeba histolytica.*

Treatment of bacillary dysentery has been by giving a mixture of sod. sulph. ʒij, mag. sulph. ʒij, aqua ℥j. An ounce was given immediately and ʒj hourly until the stools were watery, and the dosage was then reduced to three- and six-hourly administration until faeces reappeared. For the first 48 hours fluids only were given and then a typhoid diet (200–300 calories) but containing no milk.

I thought that by now bismuth had been proved to have no therapeutic action and have never used it. In cases where other antidiarrhoeic drugs have been given I have noticed that although the diarrhoea cleared up the patients suffered for many days with intense intestinal colic.

Many papers have so far appeared on the treatment of bacillary dysentery with sulphaguanidine. This drug has been advocated because it is only absorbed to a very small extent from the intestines. In this disease, however, the bowel is acutely inflamed, and one would not expect any absorption to occur. On the contrary, the capillary walls are so paralysed by the infection that fluid passes from the intestinal wall into the lumen. In consequence, I have seen no objection to treating severe cases of bacillary dysentery with sulphapyridine for the first 48 hours, especially since the mode of action of all these sulphonamide drugs is the same. Sulphapyridine also has the advantage of being more easily obtainable out here. Large doses have been given—12 g. per 24 hours—and then followed by salines. There have been no adverse effects, and the condition has quickly come under control.—I am, etc.,

Mhow, India. GRENVILLE MATHERS, Lieut., R.A.M.C.

Foot-and-Mouth Disease in Man

SIR,—The case of suspected foot-and-mouth disease described by Dr. K. MacLeod (March 6, p. 300) was also seen by me, and I can assure Dr. Monro (April 24, p. 520) that the condition was not consistent with Vincent's angina, the diagnosis of which is a relatively simple matter once diphtheria has been eliminated, being usually an ulcerative or membranous lesion, not vesicular, as was so marked in this instance. The two conditions are so fundamentally different that Dr. H. Dlugosz (Feb. 13, p. 189) has not considered it necessary to mention specifically Vincent's angina in his differential diagnosis.

The lesions in Dr. MacLeod's case were restricted to the mouth and lips, the tongue condition differing little from what is seen there in the bovine. The peculiar odour and the marked salivation also bore out the possibility of the case being actually a human infection with foot-and-mouth disease, but without laboratory proof one is naturally unwilling to be dogmatic on the matter. Inability to obtain a history of having drunk infected milk does not mean that this did not occur, for a child, acutely ill (who incidentally lives in a crofting community), is not likely to have very accurate recollections of what she ate or drank fourteen to twenty-one days before, and, as Dr. Dlugosz's article illustrates, ingestion of infected food is not absolutely necessary for infection although it is the most likely means.

The high resistance of man is well borne out in the case of the epidemic in this country where a dairy herd supplying approximately 20 gallons of raw milk to a county town did not produce a known case of the disease, in spite of the fact that doctors were on the look-out for such.—I am, etc.,

Dingwall, Ross-shire J. LANDESS HORNE, M.D.

First Aid for Fractured Spine

SIR,—Following my letters on this subject in the *British Medical Journal* (Oct. 31, 1942, p. 529, and Dec. 19, 1942, p. 744) I submitted the matter to the executive committee of the British Orthopaedic Association. It was discussed at the last meeting held at the end of February, and the following considered opinion was given: "The executive committee decided to give authoritative support to the view that patients with suspected spinal fractures should be shifted and moved in such a way as not to be folded either backwards or forwards. The patient should be disturbed as little as possible, being transported 'as he lies.' From the point of view of the spinal injury, we are of the opinion that there is no indication for change of position from face to back or vice versa." I am sure all interested in this important matter will welcome this authoritative opinion on a difficult problem and will feel grateful for a clear and definite ruling. In view of this ruling the modified Clarke-Moir method of first-aid treatment for fractured spine or suspected fractured spine is being submitted to the B.R.C.S. and the Orders of St. John and St. Andrew for their consideration as to whether they can incorporate it in their teaching.—I am, etc.,

J. L. MOIR, M.B., Ch.B.,
Lt.-Col., Zone Medical Adviser, Anglesey Home Guard;
County Medical and County Civil Defence Officer,
Anglesey Branch, B R C S.

Admissions to Mental Wards in Wartime

SIR,—I read with interest Dr. F. Hopkins's account of the decrease in admissions to mental observation wards during the war (March 20, p. 358). Dr. Hopkins's impressions are identical with my own, but I had hoped that he would be able to produce some significant statistics bearing on the subject. It is almost impossible to obtain any such data for the London area, because at various times during the war patients from the same area have necessarily been directed to different observation units, and there is some overlap in the areas served by different units. In the Liverpool area, however, where all cases were received in one unit, it should be possible to obtain population figures from the Ministry of Food authorities and to correlate these with the figures of admissions. If this were done the statistics published by Dr. Hopkins would acquire considerably more value.

At present it is not clear to me that the conclusions drawn from the published data have an adequate basis. Far too many variables are involved. It is, in my opinion, unwise to take the number of certified cases as a reliable guide. The considerations governing certification have altered somewhat owing to war conditions. Thus a patient with early senile dementia who might well have been cared for at home in peacetime may now be impossible to cope with owing to a risk of offences against the black-out regulations, or because he or she is too much of a liability under air-raid conditions, or because all the female relations are now at work and there is nobody at home to be responsible for the patient. Thus a considerably reduced population may be sending to hospital the same number of certifiable patients.

Proof of a reduction in the incidence of neuroses as a result of wartime conditions is of the utmost sociological significance for the reasons which Dr. Hopkins has indicated, and I hope that figures correlated with the population served will be published from his and other such units.—I am, etc.,

St. Mary Cray, Kent. BRIAN H. KIRMAN.

Scientific Freedom and Social Medicine

SIR,—Many of those who work in municipal hospitals will be in agreement with several of Dr. Geoffrey Bourne's general principles, but some of his points would not bear cross-examination. The picture produced of the municipal hospital has unduly sombre colours, while that of the voluntary system is somewhat too rosy, as no drawbacks are mentioned, though admitted by others. Municipal hospital staffs have considerable experience and appreciation of voluntary hospitals, but staffs of voluntary hospitals may only have a nodding acquaintance with municipal hospitals, which may be insufficient to draw definite conclusions.

In his criticism of the municipal hospital Dr. Bourne has focused attention upon the medical superintendent. There may be medical superintendents who sometimes are not sufficiently tactful in carrying out some of their duties, just as there may be consultants who are sometimes forgetful of their hospital commitments. Similarly, examples could be quoted of doctors in any branch of medicine who sometimes interpret their duties inadequately; and cases could be stated, equally easily and fallaciously, to indicate that any particular system is essentially wrong. But all these matters call for adjustment in the individual, and isolated incidents cannot be the basis of a sound judgment.

There is no difficulty with regard to the formation of medical staff meetings in municipal hospitals so far as medical superintendents are concerned, for they are in favour of such a step. Senior staff have complete freedom of clinical action, but useful decisions could be taken at such meetings, and they would help to give consulting staff a closer interest and a more integral part in these hospitals with mutual benefit.

Both municipal and voluntary hospitals have their own advantages and disadvantages. Both exist solely for the care of the sick, and in their individual approach to the problem it is probable that neither has an all-round view, and each can learn something from the other. Voluntary hospitals have performed an inestimable service to the community, sometimes inadequately appreciated, but the rise of an alternative service has shown up certain points, arising from the fact that they have too much work to do. The enormous growth and improvement of municipal hospitals in the last twelve years and the confidence shown in them by practitioners and the public could hardly have been achieved if there were something radically wrong with their internal hospital medical arrangements.

The voluntary hospital system is an old and venerable tree that has borne much good fruit, but after so many years it is natural that there is some dead wood to cut away. In place of this should be grafted some of the vigorous growth of the new system, and together they will form a structure of unequalled service to the community.—I am, etc.,

Derby. R. G. COOKE.

SIR,—Dr. Geoffrey Bourne (April 17, p. 490) asks me three specific questions, to which I gladly reply.

1. I do believe in democracy in science as in everything else—that is, in real unrestricted freedom of speech and criticism.

2. I do not believe in placing autocratic power as regards medical affairs in the hands of any individual, be he medical superintendent or anyone else. Dr. Bourne in the letter just referred to states: "In plain fact the medical superintendent in council and municipal hospitals has absolute power as regards medical affairs as well as administratively." I can find no evidence for this statement. Rule 391 of the Hospitals and Medical Services Committee of the L.C.C. deals with the duties of a medical superintendent. It has twenty-eight sections, and the only one that could possibly be construed in the way Dr. Bourne suggests is Section VI, which reads as follows: "Organize and supervise the work of the medical staff of the hospital and be responsible for the due and punctual attendance upon the patients and for the giving of the requisite directions as to their treatment, nursing, and diet by the medical officers, and for the condition of the wards." It is difficult to understand how Dr. Bourne can say that this gives to the medical superintendent "absolute power as regards medical affairs as well as administratively." Rightly or wrongly it has been our traditional method to evolve from one system to a better by gradual steps and stages. In a sense, therefore, the master of a Poor-Law workhouse may be looked upon as the remote ancestor of the medical superintendent of a council hospital. But the absolute power of the medical superintendent is gone, although he is still administratively in charge of the institution.

3. I believe that medical committees should be instituted in every hospital, and that they should have local freedom to elect their own chairmen and officers, and that machinery should be devised, where it does not already exist, so that these committees may convey their opinions directly to the body in control of the hospitals in which they work.

Dr. Bourne goes on to say, referring to myself: "If his official position makes it impossible for him to reply, I suggest that he ascertains the answers from his lay authority with their permission to make them public." Whether this foolish remark arises from ignorance or prejudice I do not know. I am a member of the honorary staff of a voluntary hospital and a part-time surgeon under the E.M.S. scheme. I have criticized the voluntary hospitals and the E.M.S. scheme freely without let or hindrance and shall continue to do so if necessary. I am also a member of the L.C.C. and chairman of its Hospitals and Medical Services Committee. The L.C.C. is a democratic organization, every member of which is free to express his views, although, obviously, where decisions have to be made it is the view of the majority that prevails. I do not know to which of these three "lay authorities" (or any other) Dr. Bourne refers.—I am, etc.,

Northwood. SOMERVILLE HASTINGS.

A National Medical Service

SIR,—We do not deny that the present medical services are far from perfect, and no member of the profession would impede any alterations calculated to achieve the maximum possible efficiency. It is the stated policy of the present Government (elected in 1935) to institute a unified medical service; but approximately one-seventh of the total population of these islands, selected by medical boards from a selected age group, require the attentions (under a unified medical service) of about a quarter of the total profession (*Lancet*, April 10, 1943, p. 469). The success of any medical service must depend on the active and willing co-operation both of the lay public and of the profession. But at present the most virile section of the public (lay and professional) is disfranchised, and has not been, nor can be effectively, consulted in wartime.

We suggest, therefore, that the present time is inappropriate for the Government to foist a new medical service upon a public, unsuspecting, and gagged by the bureaucratic restrictions necessary to the successful conclusion of the war.—We are, etc.,

DOUGLAS ROBERTSON.
G. O. RICHARDSON.
G. A. SMART.

Kenny Treatment of Poliomyelitis

SIR,—My attention has been drawn to the leading article in the *Journal* of Nov. 28, 1942 (p. 639), entitled, "Kenny Treatment of Poliomyelitis." In reference to this matter I consider it necessary to correct certain statements contained in this article.

In the first instance my contribution to medicine is not a reformed treatment for recognized symptoms but a new concept of the symptoms. With regard to this I would refer you to the bulletin read at the staff meeting of the Mayo Clinic, Aug. 12, 1942, and presented by Dr. Frank Krusen, professor of physical therapy, Mayo Clinic, Rochester. Dr. Krusen admits that when he heard my theory with regard to these symptoms he thought I was unbalanced, but when I invited him to come to Minneapolis and see for himself he, with the heart and mind of the true physician, readily accepted the invitation, and, subsequently, requested to be enrolled in the first physicians' class to be held under the auspices of the Department of Physical Therapy and Orthopaedic Surgery, School of Medicine, University of Minnesota, during which time the concept was presented to him and the treatment for this new concept demonstrated and the results shown. Dr. Krusen's report reads: "Her ideas are original and she should be given full credit for having developed a new and extremely interesting concept of the symptoms of early poliomyelitis and the proper management of these symptoms. The Kenny method merits the close scrutiny of every physician."

Your article makes reference to the main points of my treatment in the acute stage. I would respectfully draw your attention to the fact that patients were not admitted to Queen Mary's Hospital in the acute stage. The patients treated in this institution were transferred from the infectious diseases hospital after the acute stage was over, and in a great many instances were not admitted to Wards A7 and 8, where the work was being carried out, but were hospitalized in E3 and 4 until the London County Council inquired of the parents if they were willing that their child should be submitted to the new type of treatment. This took quite a while. The parents generally waited to consult the parents of the children who were already receiving treatment, after which they would give their consent. By this time in quite a number of the cases the early symptoms had accomplished their deadly work. I attempted to explain this to the committee, and also that spasm was a damaging feature, but the committee were non-receptive. The reply I received was, "Spasm? What do you mean? This is a new one on us." This remark was passed by Mr. Fairbanks, and nothing further materialized. This committee was formed in Nov., 1937, during my absence in Australia.

I returned to England in April, 1938, and met the committee twice—in April, 1938, and May, 1938. The report referred to was presented in June, 1938. I left Queen Mary's Hospital the following month and returned to Australia. The conferences held at Queen Mary's Hospital by the committee during the two afternoons of their visit in April and May and their final conference in June, before the presentation of their report, were held *in camera.* I was not invited to be present.

I would also like to state that you are mistaken if you think that I was well pleased with my reception by the L.C.C. I was well pleased with the earnest endeavours of the technicians to grasp the technique taught them, which prevented deformities despite the abandonment of the paramount principle of orthodox procedures—immobilization. I was bitterly disappointed at the refusal of the L.C.C. to allow the Kodak Company to reproduce the film picture of my work at Carshalton, for which I myself was willing to pay in order that I might take it back to Australia. Sir Earle Page, Minister of Health of the Commonwealth of Australia, had made the request to me. I also noticed that you make reference to a report submitted by Dr. Starr, given to the Minister of Health, New South Wales. I think it is well known that I had dissociated myself from this work with Dr. Starr long before this report was published.

I notice that you have made no mention of the report submitted by Drs. Forster and Price of Melbourne, Australia, in which they state: "(1) Miss Kenny lays great stress on the condition of muscle spasm, its prevention and cure. We think her views on this subject require careful consideration. (2) Stiffness is a troublesome feature in the cases treated by the orthodox methods and entirely absent in the cases treated under Miss Kenny's supervision. The reason why should be earnestly sought. (3) Expected deformities from muscle imbalance did not occur, but did occur in our own splinted patients we ourselves treated or received from other surgeons. This calls for comment."

You also quote: "In December, 1941, the *Journal of the American Medical Association* made this cautious statement: 'Adoption of the Kenny technique represents an elaboration of well-recognized principles,' and, 'If there is any revolutionary element it consists in its abandonment of early rigid splinting and the adoption of continuous and meticulous hydrotherapy and physical therapy to maintain the function of muscles, at the same time producing increased comfort to the patient.'" This statement appeared (like your own) in the editorial, and was presented by one whom I had never met or at that time seen. You omitted to quote the statement made in the issue of this journal for June 7, presented by the professors of physical therapy and orthopaedic surgery, University of Minnesota, who had observed the work and made their report from observation, reading: "According to this concept the cardinal symptoms of infantile paralysis are to use her terms muscle spasm, muscle incoordination, and mental alienation. This is opposed to the usual concept, where the cardinal symptom is flaccid paralysis without muscle spasm or incoordination. The presence of spasm has been demonstrated in 100% of the cases." This report further refers to this matter and states the concept is original and unconventional.

You also state: "In the textbooks it is recognized that in poliomyelitis there is gross disorganization of muscular function with overaction (which is another way of saying spasm) of unparalysed muscles." Again, "That mental alienation is no new idea is well shown by the following sentences from Jones and Lovett: 'Muscle training is fundamentally an attempt to restore a cerebral motor impulse to a muscle, an impulse which has been either impaired or lost during the acute stage of poliomyelitis.'" It is made clear in this presentation that the writer of this article is not familiar with the Kenny concept. He or she refers to overaction of unparalysed muscles. These are in orthodoxy supposed to be normal muscles contracting and pulling the skeleton into deformity. These muscles are in reality the sick muscles, not the non-paralysed one. They are the muscles that require careful nursing. The pain, spasm, and shortening causing the deformities are centred in these muscles, and the alienation of the opponents is caused through this condition, not as stated by the writer in his paper.

The writer further states in reference to Lovett and Jones: "They knew all about incoordination, overaction or spasm of muscles, cerebral impulses, and the scrupulous care required for their protection and re-education." The presentation of the muscle condition as accepted by Lovett and Jones is reproduced in *Public Health Bulletin*, No 242, U.S.A. Public Health Headquarters, by the pupils of Dr. Lovett, and reads: "The muscle itself is never affected by the disease but is comparable to an automobile with its battery stolen. The muscle is loose and flaccid and hangs like a hammock between its points of origin and insertion." This is the Lovett-Jones concept for which splinting was applied to prevent the strong supposedly normal muscles from pulling the weak, flaccid muscles. Nurses were warned that to leave a splint off the part and the supposedly flaccid muscles unsupported even for a short time would mean prolonging treatments for months.

These supposedly flaccid and paralysed muscles were the muscles referred to in the report of Dr. Alfred Deacon, orthopaedic surgeon, Children's Hospital, Winnipeg, Canada, which appeared in the *Canadian Public Health Journal*, August, 1941, reading: "We were astounded to see Miss Kenny restore what we had recorded as completely flaccid and paralysed muscles to full function in the course of a few minutes by restoring mental awareness" This was not done by directing the patient's mind to the part. The motor pattern had to be restored first. The patient is not asked to think. If they could think there would be no necessity to tell them to do so. The procedure reaches further than that. The concept can be best explained in the language of the scientist and research worker, Dr. Hipps, who wrote: "You have found symptoms and visible findings in this disease, infantile paralysis, that we had no idea existed. You have demonstrated to me a disease I did not know existed."

You are very much mistaken if you think the American workers are giving extravagant credit to this presentation or that it is old ideas with new names. There have been upward of 300 doctors attending the classes at the University of Minnesota, all of whom have practising technicians also trained in Minneapolis from the United States of America, Cuba, and Canada. Many have film pictures of the results and that of their orthodox patients, showing 60% more recoveries in the patients treated by the method evolved for the new concept, which has been acknowledged by the observers to be diametrically opposed to the orthodox concept.

The author of the article in your *Journal* refers to Jones and Lovett as the orthodox authorities on this disease. The two physicians referred to in this letter—Drs. Krusen, Mayo Clinic, and Pohl, Minneapolis—were trained in this school, and upon my arrival in Minnesota, U.S.A., were religiously practising their technique. Both thought I was unbalanced mentally when I presented my concept, and both, being true physicians, now acknowledge their mistake. The investigation of my work and theories was carried out at the suggestion and under the direction of Dr. Wallace Cole, professor of orthopaedic surgery, University of Minnesota, and was assisted by Dr. Miland Knapp, professor of physical therapy. I would gladly welcome the author of your article to Minneapolis as representative in the interests of humanity and the well-being of the people of England. I think this would be a laudable undertaking.

I have requested the Bruce Publishing Company to forward to you the book entitled: *The Kenny Concept of Infantile Paralysis and its Treatment.* You will see in the foreword, written by Dr. Frank Ober, professor of orthopaedic surgery, Harvard University, and president of the American Orthopedic Association, that: "Sister Kenny puts great emphasis on muscle spasm in the affected muscles. One does not find mention of muscle spasm in textbooks, but there is no doubt that it is present, and is a great factor in the production of early deformities unless relieved. Mental alienation of muscles is another term used in the book, and does occur even in other conditions in which there is no paralysis." Dr. Ober was a colleague and pupil of the Jones and Lovett you refer to. This evidence, presented from indisputable authority, will go far to explain the reason why deformities did not occur in the patients treated by this method under my supervision at Queen Mary's Hospital, Carshalton, and every other institution that adheres to the method when immobilization, the paramount principle of orthodox procedures, to prevent this condition was abandoned.

You will learn from the above observation and statement that my concept is not a new term for old ideas. It is the muscle affected that is in spasm and the non-affected one that is alienated. Therefore, the explanation given by Drs. Cole and Knapp two years ago is supported to-day by Dr. Frank Ober and the hundreds of others that have come to listen and learn. It is explained in the presentation of Dr. Frank Krusen, Mayo Clinic, Rochester, and already quoted in this letter. I would gladly welcome a doctor and technician from Queen Mary's Hospital to finish their training, also from any of the Australian clinics that are equipped with a partially trained staff. Units are being enrolled from the South American Republics, Cuba, Canada, and China. The University of Minnesota would gladly share this message of healing with the rest of the world.—I am, etc,

Minneapolis. ELIZABETH KENNY.

Staffing of Miniature Mass Radiography Units

SIR,—With reference to Dr. Norman Henderson's letter (April 17, p. 488), reduction in radiographic exposure time when employing mobile power unit is due to a variety of reasons. A specific input voltage at a high frequency permits precise calculation of iron and copper, and, more particularly, allows reduction of core and windings in the design and construction of the high-tension *x*-ray transformer. Portability of transformer, therefore, is the logical reason I have specified, in certain instances, a high cycle input in self-contained mobile *x*-ray units (*Brit. J. Radiol.*, 1934, **7**, No. 79).

I would not advocate the adoption of non-standard frequency in any contemplated wide use of mobile miniature radiographic units. Standardization must be preserved throughout the scheme whether the apparatus be used on the public supply mains or the mobile generator. Improvement in radiographic exposure time is due primarily to distortion of wave-form in the alternator on load, resulting in a "peaky" rather than true sine wave. Under certain conditions an induction coil effect is produced which varies according to the regulation of the transformer.

I apologize for dogmatizing on a technical subject through the columns of a medical journal.—I am, etc.,

London, S.W.1. H. T. Ferrier.

Maintenance of the Dependants of Tuberculous Patients

Sir,—The Committee on Tuberculosis in Wartime in their report (M.R.C. Special Report Series 246, 1942) made the suggestion, now adopted by the Minister of Health (Memo. 266T, April, 1943), that financial aid from public funds should be afforded to the dependants of tuberculous patients during the period of the breadwinner's invalidity. It is now more than 40 years since this suggestion was made to the Corporation of the City of Manchester by their then medical officer of health, the late Dr. James Niven. A passing reference to the incident is recorded in his *Observations on the History of Public Health Effort in Manchester* (Jno. Heywood, 1923).—I am, etc.,

Ministry of Health, Whitehall, S.W.1. J. R. Hutchinson.

Obituary

C. LAMBRINUDI, F.R.C.S.

Orthopaedic Surgeon to Guy's Hospital

We regret to announce the sudden death on April 21, at Mayfield, of Mr. C. Lambrinudi, orthopaedic surgeon to Guy's Hospital and consulting orthopaedic surgeon to Queen Mary's Hospital, Carshalton, who had made many valuable contributions to his branch of practice.

Constantine Lambrinudi was born in 1890 and entered Guy's from Christ's College, Cambridge, in 1910. His medical studies were interrupted in 1912-13 by two periods of service during the war in the Balkans. He qualified M.R.C.S., L.R.C.P. in 1914, and was in turn assistant house-surgeon to Mr. C. H. Fagge, out-patient officer, and house-surgeon to Sir Alfred Fripp. During the last war he served again with the Greek Army and later as a medical officer in the Royal Flying Corps. After working for a year as part-time demonstrator of physiology at Guy's and surgical registrar at the Royal Free Hospital he took the F.R.C.S. in 1921, and was chief clinical assistant and registrar in the orthopaedic department at Guys from 1923 to 1928, when he was appointed assistant orthopaedic surgeon; on the death of Mr. Trethowan in 1934 he became orthopaedic surgeon in charge of the department. Lambrinudi was honorary secretary of the Orthopaedic Section of the Royal Society of Medicine in 1933-5, and served on the Council of the British Orthopaedic Association. He described a new operation for the correction of drop-foot in the *British Journal of Surgery* in 1927, and wrote on the "Use and Abuse of Toes" in the *Clinical Journal*. At the Annual Meeting of the British Medical Association in 1934 he opened a discussion in the Section of Orthopaedics on adolescent and senile kyphosis, and this paper appeared in the *British Medical Journal* of Nov. 3, 1934.

A tribute published in *Guy's Hospital Gazette* recalls the fresh and unbiased outlook which Lambrinudi brought to every problem that he tackled.

> "The result was not only the gift to orthopaedics of a considerable number and variety of real advances, which have already been generally accepted, but also original and stimulating thought on nearly every subject which he touched. He had also that other quality of greatness—simplicity in ideas. . . . He held that the chief function of the specialist was to explore the uncharted, or only partially understood, regions of medicine, to elucidate and simplify them, and return the knowledge so obtained to medicine as a whole. He held that there were no principles of orthopaedics as opposed to principles of medicine. There were only principles of medicine, which in orthopaedics should be applied to the restoration and maintenance of the function of locomotion, using the term in its widest sense. Always he laid stress on function as the only true guide in treatment, and not only function of the body as a whole, but also its proper functioning in relation to its social environment. It was for this reason that he attached so much importance to the almoner's department, and it was for the same reason that he instituted the employment of the visiting masseuse in connexion with hospital practice—an innovation in which Guy's has led the field."

Mr. Frank St. J. Steadman, senior dental surgeon to the Royal Dental Hospital, London, died suddenly on April 11, aged 63. He was a student at Charing Cross Hospital and took the L.D.S. in 1902, following this with the M.R.C.S., L.R.C.P. in 1907, and the D.P.H. in 1911. Devoting himself to the practice and teaching of dental surgery, he was appointed to the staff of the Metropolitan Hospital and the Belgrave Hospital for Children, and lectured in histology and practical dentistry at the National Dental Hospital. During the last war Mr. Steadman served over-seas in the R.A.M.C.(T.A.), and reached the rank of major when holding the administrative post of D.A.D.M.S., 20th Corps. After returning to civilian life he became lecturer in dental diseases in childhood, on local anaesthesia, on bacteriology, and on oral surgery, at the Royal Dental Hospital. He also examined in dental surgery for the Universities of London and Bristol. In 1937 he was president of the British Society for the Study of Orthodontics, and in 1939 president of the Odontological Section of the Royal Society of Medicine.

Dr. Ernest Charles Jennings died at Newton Abbot on March 13 as the result of a motor accident. He was 65 years of age. He studied medicine in Dublin, and qualified at the Royal College of Surgeons in 1904. He held resident appointments in England, and went to Australia in 1911, where he did much pioneer work in establishing medical services in the remote districts. He practised in Queensland and New South Wales. In 1928 he returned to England, and took up practice at Bracknell. Two years ago he retired and went to Devonshire. Dr. Jennings was a member of the B.M.A., and always took an interest in all medical work until the time of his death. His cheerful and lively personality endeared him to all with whom he came in contact, and he will be much missed by his colleagues and friends. His wife survives him.

The Services

Capt. (temp. Major) G. H. G. Hope, R.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in the Middle East; and Capts. (temp. Majors) L. E. C. Davies and J. R. Kellett, R.A.M.C., have been appointed M.B.E. (Military Division) in recognition of gallant and distinguished services in the South-West Pacific.

CASUALTIES IN THE MEDICAL SERVICES

Wounded.—Capt. N. J. H. Davidson, R.A.M.C.

Missing since the Fall of Singapore, now Officially Reported Interned in Malaya.—Dr. M. A. X. Cocheme, Colonial Medical Service.

Missing, Presumed Killed.—Surg. Lieut. Philip Alan Rees, R.N.V.R.

DEATHS IN THE SERVICES

Surg. Rear-Admiral Herbert Reginald Harry Denny, C.B., R.N. (ret.), died on April 20 as the result of a motor accident at Plymouth, aged 66. He was educated at Guy's Hospital, and, having obtained the Conjoint Board medical qualification in 1899, joined the Royal Navy in the following year. He served throughout the war of 1914-18 in the Grand Fleet and subsequently became S.M.O. of the Royal Naval Hospital, Cape of Good Hope. In 1931 he was promoted to be rear-admiral and in 1935 he was appointed honorary surgeon to the King. He received the C.B. (Mil.) in 1932 for his long and distinguished services. After his retirement in 1935 he resided at Plymouth, and he was engaged in war work at the time of his fatal accident.

Lieut.-Col. Walter Rothney Battye, D.S.O., I.M.S. (ret.), died, aged 69, at Parkstone on April 27 after a long illness. He was a highly qualified and able officer who had a varied career. He obtained an entrance exhibition and gained medals at University College, London, and took the B.Sc.Lond. in 1898, with honours in zoology, the M.B., B.S. in 1897, the M.S. in 1908, and the F.R.C.S. in 1909. He entered the I.M.S. in 1898, gaining the second place, and won the Parkes Memorial Medal at Netley. After serving with Indian cavalry regiments in India he saw active service in China during the Boxer rebellion in 1900. Three years later he entered the civil branch of the I.M.S. in the coveted political department, served during the next ten years in Persia and in Rajputana, and became chief medical officer, Central India, residency surgeon, Indore, and superintendent of the King Edward Hospital and Medical School, where his exceptional qualifications found scope. During the war of 1914-18 he served in Egypt, and in the Dardanelles until the evacuation, and was mentioned in dispatches four times, awarded the D.S.O., and made a Chevalier of the Legion of Honour. After duty in France he was promoted to be D.A.D.M.S. at Baghdad, and subsequently became Secretary for Health and Director of Civil Medical Services, Mesopotamia, in 1919. After this varied and distinguished career he retired in 1929, but served further as medical superintendent of King George V Merchant Seamen's Memorial Hospital, Malta. He was the author of papers on plague, spinal anaesthesia, the treatment of Anzac wounded, and on the climate and health of Meshed, Persia. His life's work well illustrates the great opportunities the Indian Medical Service in its palmiest days offered to men of his ability and energy, of which he took the fullest advantage.

Lieut.-Col. ALEXANDER CLIFTON CRAIGHEAD, I.M.S., died at sea through enemy action in March, 1943, aged 54. He studied medicine at St. Andrews University and passed the final M.B., Ch.B. examination in 1914. He became a temporary lieutenant, R.A.M.C., during the last war in 1916 and obtained a permanent commission as captain in the I.M.S. in 1919. In 1925 he took the D.T.M.&H. with distinction, and gained the Duncan medal. He served in the Indian Research Department and became assistant director, Central Research Institute, Kasauli, and was joint author of an investigation into the value of an etherized vaccine.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on May 6 the honorary degree of D.Sc. was conferred on Dr. Joseph Trueta, formerly Director of Surgery in the University of Catalonia, who came to England in 1939 and in 1940 was appointed by the Minister of Health to an advisory post at the Wingfield-Morris Orthopaedic Hospital, Headingley.

UNIVERSITY OF CAMBRIDGE

Albert Charles Chibnall, Sc.D., F.R.S., of Clare College has been elected Dunn Professor of Biochemistry from Oct. 1, 1943, in succession to Sir Frederick Gowland Hopkins. Dr. Chibnall has held the chair of biochemistry at the Imperial College of Science and Technology, London, since 1936.

At a Congregation held on April 30 the following medical degrees were conferred:

M.D—(by proxy) J. W. Parks, T. E. Jones-Davies, (in person) H J Wallace.
M.B, B CHIR.—(by proxy) L. G Kingdom, B Pownall, J Lomas

Titles of the degrees of M B., B Chir. were conferred by diploma in March on E. Tylden of Girton College, and in April on H. C. Mason of Newnham College.

The Professor of Anatomy gives notice that applications for the Marmaduke Sheild scholarship in human anatomy are to be sent to the Registry by May 20 in the present term.

UNIVERSITY OF LONDON

The membership of the following medical representatives of Convocation has been continued until May, 1944: *Medicine*, Sir E. Graham-Little and Major-General P. H. Mitchiner; *Science*, Prof. M. Greenwood, D.Sc., F.R.S.

The following candidates have been approved at the examination indicated:

POSTGRADUATE DIPLOMA IN PSYCHOLOGICAL MEDICINE—[1]G H. H Benham. *Part I*: A. H D. Hunter, A. W. MacLeod

[1] With Mental Diseases (Psychiatry)

UNIVERSITY OF GLASGOW

The degree of Doctor of Medicine (M.D.) with commendation was conferred by diploma upon James Stewart, M.B., Ch.B., on April 17.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a meeting of the College, held on April 29, with Lord Moran, President, in the chair, the following were elected Fellows:

C. R. Burns, M D. (New Zealand); B. Maclean, M.D. (Newcastle, Staffs); Janet K. Aitken, M.D. (London); H. L. Wilson, M.D. (London); H. Joules, M D. (London); L. Minski, M.D. (Sutton, Surrey); A. G. Watkins, M.D. (Cardiff); Brig F. M. Lipscomb; Major-Gen. Sir P. S. Tomlinson, C B., D.S.O.; C. T. Andrews, M.D (Truro); G. A. Elliott, M.D. (Capetown); Reginald Ellis, M.D. (Manchester); M Kremer, M D (London); G. D Kersley, M.D. (Bath); D. U. Owen, M.D. (Liverpool); R. Bodley Scott, D.M. (London); W. E. Snell, M.D. (London); F. S. Fowweather, M.D. (Leeds); R. H. Parry, M.D. (Bristol); K. Robson, M.B. (London); J. L. Lovibond, M.B. (London); P. J. Kerley, M.D. (London); Denis J. Williams, M.D. (London); W. Ritchie Russell, M.D. (Edinburgh); J. W. Bigger, M.D. (Dublin); Noah Morris, M.D. (Glasgow); J. E. Gordon, M.D. (Harvard); James M. Mackintosh, M.D. (Glasgow); Charles McNeil, M.D. (Edinburgh); L. C. Montgomery, M.D. (Montreal).

Dr. J. L. Livingstone was elected an Examiner in Pathology.

The following candidates, having satisfied the Censors' Board, were admitted Members:

J. L. Bates, M B., J. L. D'Silva, M.B, T. S. Eddie, M.B., L. A. Hawkins, M B, J C Herapath, M.B., A. W. J. Houghton, M.B, Major R. P. Howard, M.D, R.C A.M.C., J. S Lawrence, M.D., R. Marshall, M.D., Surg Lieut.-Cmdr. G. J. Murray, M D., R.N.V.R., Sheila M. Newstead, M.B, Capt. O. R. L. L. Plunkett, L.R.C P., R.A.M.C., K. O Rawlings, M B, F. Ridehalgh, M B, Sheila P. V. Sherlock, M B., J. V. Sparks, L.R.C.P., J. R Tasker, M.B, W. G Tillmann, M B., A. W W. B Woods, B M.

Licences to practise were conferred upon the following 238 candidates (including 30 women) who had passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the necessary by-laws:

D. G. Abrahams, N. Ambache, I. B. Amin, R. E. Arango, E. L. Arnold, D. C Artingstall, Janet F Atkins, D. R. F Atkinson, J. Attenborough, G. B. Badock, R. A J. Baily, Ursula M Baines, E H. Zerny, J Zimmermann

Diplomas in Medical Radiology were granted, jointly with the Royal College of Surgeons of England, to the five persons whose names were published in the *Journal* of March 20 (p. 368), as were the names of the eleven persons who were granted Diplomas in Ophthalmic Medicine and Surgery. Diplomas in Child Health were granted to the fifteen persons whose names were published in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of April 24 (p. 524).

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of Council held on May 1, with the President, Sir W Fletcher Shaw, in the chair, the Honorary Fellowship of the College was conferred on Sir Wilson Jameson, Chief Medical Officer of the Ministry of Health, in recognition of his services to obstetrics and gynaecology

Gladys Hill and N. L. White have been admitted to the Fellowship, and the following were admitted to the Membership: Janet E. Bottomley, Phillis Dingle, Marjorie O. Dunster, L. Resnick, G. S. Sturtridge, K. G. P. Worner.

At the annual general meeting of the College, held on May 1, with the President in the chair, the following were elected to Council in place of those retiring by statutory rotation: *Representatives of the Fellows*: A. J. McNair, A. A. Gemmell, J. Chassar Moir, R. H. J M. Corbet. *Representatives of the Members*: B. L. Jeaffreson, J. S Quin

Medico-Legal

CRIMINAL NEGLIGENCE: A CONVICTION QUASHED

A recent judgment of the Privy Council re-emphasized the distinction between the negligence which gives grounds for a civil action and that which exposes a person to criminal penalty. A West African medical practitioner, Dr. J. O. Akerele, was touring the Owerri Province of Nigeria and treated at two villages a large number of patients for yaws. He used injections of sobita, a preparation of bismuth sodium tartrate extensively used for this purpose. Of the 57 children he treated at one of the villages 10 died.

The Trial in West Africa

He was charged before an assistant judge with the manslaughter of one of the children, Kalu Ibe; with reckless and negligent acts in giving medical treatment to the child in a manner so rash or negligent as to endanger human life or to be likely to cause harm; and with reckless and negligent acts in dispensing or administering medicine or poisonous or dangerous matter to the child. Another medical practitioner who had treated the child ten days after the inoculation, and a district mission worker, gave evidence that the boy had suffered from stomatitis induced by bismuth poisoning, and this medical witness and another doctor inferred that the death was due to an overdose. Dr. Akerele maintained in his defence that Kalu Ibe had been peculiarly susceptible to a dose which would have been harmless to a normal child. He said he had dissolved the powder in sterile water and carried a 20-oz. bottle made up for the day's work. After the illness had shown itself he returned, provided mouth-wash and milk at his own expense, and tried unsuccessfully to enlist an assistant to continue the treatment.

The judge found that the doctor had negligently prepared too strong a mixture and that his negligence was criminal. Summing up, he said that the dissolving of sobita in water to a certain strength evidently involved no particular technical finesse, but the accused in giving these injections had managed to make at least 11 persons gravely ill with the most revolting symptoms. One would have thought (he said) that in the circumstances he would at least make as certain as was humanly possible that he injected the correct dose. The judge concluded that the doctor had acted with a degree of negligence that could only be described as criminal. He found him guilty of manslaughter and sentenced him to three years' hard labour; not guilty of the second charge (negligent medical treatment), but guilty of the third charge (negligence in administering medicine), for which he imposed a fine of £100. The West African Court of Appeal quashed the sentence on the third charge, affirmed the conviction for manslaughter, but varied the sentence to a fine of £500. The Board of Examiners for Nigeria erased the doctor's name from the local medical register.

Appeal to Privy Council

Dr. Akerele appealed to the Privy Council, and the Board found unanimously that he had been wrongly convicted.[1] They referred to the leading cases on criminal negligence, and emphasized that criminal negligence must be gross, and that neither a jury nor a court can transform negligence of a lesser degree into gross negligence merely by giving it that appellation. There is a difference in kind as well as of degree. In *R. v. Crick*,[2] Chief Baron Pollock said it would be most fatal to the efficiency of the medical profession if no one could administer medicine without a halter round his neck; and the Board stressed the care which should be taken before imputing criminal negligence to a professional man acting in the course of his profession. They regarded it as unfortunate that the two doctors called for the Crown were accustomed to use N.A.B. and had little, if any, practical experience of sobita, with the result that the court had no evidence on the excess of strength in the mixture which would produce the observed consequences in a normal patient, nor of how widespread among the medical profession is or ought to be the knowledge of the danger of an overdose. The known margin of error was nowhere referred to.

The only negligence on which the Crown could rely was the single act of dissolving the powder in water. It was immaterial that the symptoms were revolting and that many people were made ill; the act had already taken place and its consequences could not add to its criminality. The negligence to be imputed depended upon the probable, not the actual, result. The judge had nowhere stated in what he found the negligence to consist unless in its fatal consequences in so many persons. He had imputed to the accused repeated acts of negligence as if the doctor were to be blamed for want of care in each injection instead of for the one act of carelessness in preparing the mixture. The Board could not accept the view that criminal negligence is proved merely because a number of persons have been made gravely ill and a high degree of care has not been exercised. In their view the distinction between civil and criminal liability had been inexactly drawn, the ground of the criminal charge ill defined, and the instances of negligence increased from one to many by imputing a fresh act of negligence in the case of each death. They therefore advised the King to allow the appeal and quash the conviction.

The scanty records of criminal prosecution of doctors for negligence show how rare criminal negligence is in medical practice, and how grave a degree of recklessness has to be committed to bring a doctor within reach of the law.

THE CHURCH CELLAR MURDER

At a meeting of the Medico-Legal Society on March 25 Dr. C. Keith Simpson gave an account of the means taken to identify the victim in what was known as the Baptist church cellar murder, for which Harry Dobkin was tried recently at the Central Criminal Court before Mr. Justice Wrottesley, and was convicted and executed. Dr. Simpson said that a woman disappeared after making an appointment to meet her husband, who was in arrears of maintenance. Fifteen months later some remains were found underneath a chapel in Kennington, on premises to which the husband had access as a fire watcher. Even after such a lapse of time it was possible to decide the cause of death, which was strangling, and eventually to identify the body, although it had been dismembered, partially burned, and eventually buried in lime under the floor of the cellar. The remains were discovered by chance during demolition work and were thought at first to be those of an air-raid victim.

Identification of Victim

When the remains were discovered, said Dr. Simpson, the head was away from the trunk, and scalp, hair, face, lower jaw, and hands and feet were missing. It was at once seen that the remains were those of a woman, for the uterus was visible, and eventually was proved to have a fibroid tumour, which turned out to be an important point in identification, for it was found that the missing woman had attended at two hospitals for an internal complaint, which was diagnosed as uterine fibroid, and had refused operation. The murderer, after having tried unavailingly to dispose of the trunk by burning, had sprinkled powdered slaked lime over it and buried it under a large slab, but the lime, instead of accelerating the destruction, had preserved the soft parts from decomposition. The stature of the victim was estimated by two methods. The body was reassembled, and after making due allowance for missing bones and soft tissues, the height was estimated as 5 ft. 0½ in., control estimations being made by Pearson's formulae and Rollet's tables, taking the length of the left humerus, the only long bone available. Examination was made by *x* rays of certain bones in order to determine age. The state of fusion between the plates of the vault of the skull, confirmed by the palate, suggested an age of 40 or 50, and the missing woman was said to have been 5 ft. 1 in. in height and to have been aged 47. The teeth of the upper jaw clinched the examination. A dental surgeon was found who was able to produce the most detailed record cards of the treatment he had given to the woman, and from his records a picture of the upper jaw was reconstructed, which proved to be a perfect reproduction of the jaw which was discovered. Further, a full-face portrait of the missing woman was found, and as the major part of the skull could also be reproduced full face, two *x*-ray photographs were standardized and superimposed, the negative of the skull and the positive of the portrait, and by giving them exactly the same width between the orbits, the portrait fitted the skull like a mask. In the general contours of vault, cheeks, and upper jaw, and in the width and breadth of the sockets and position and shape of the nose openings, there was no dissimilarity whatever.

The Cause of Death

It remained to determine the cause of death. When the voice box was dissected out it was found that there was some deep crimson clot penetrating between the tissues surrounding the upper horn of the right wing of the thyroid cartilage. Under the bruise lay a fracture of the horn, and it was reasonable to infer that the throat of the victim had been gripped with sufficient strength to break that small bone. It was a strictly confined injury commonly seen only in manual strangulation. Dr. Keith Simpson concluded by saying that the case illustrated in a classical manner the striking results which might follow even in the most hopeless-looking cases by the patient application of simple medico-legal principles of study.

No. 16

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 24.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			37					41		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the incidence of infectious diseases continues to fall—measles by 3,242, scarlet fever 288, acute pneumonia 273, whooping-cough 117, dysentery 38, cerebrospinal fever 20, and diphtheria by 13—in the week under review.

The sharpest drops in the notifications of measles were: Hertfordshire 301, Glamorganshire 282, Middlesex 240, Surrey 183, Warwickshire 182, London 181, Staffordshire 180, Lancashire 145, Carmarthen 133, Durham 130, Yorks West Riding 124, Bedfordshire 122, Kent 113, Yorks North Riding 103. A few counties reported a higher incidence: Cornwall by 86, Leicestershire by 79, Derbyshire by 53.

Although there were 117 fewer cases of whooping-cough, fluctuations among the counties were considerable. The combined totals of the divisions of London, South-East, West Midlands, North Midlands, and Northern Counties showed an increase of 108. The only large variations in the county totals were decreases in Lancashire of 59, and in Cheshire of 46.

Scarlet fever and acute pneumonia declined in incidence throughout the country, whilst the trend of diphtheria underwent little change.

The 69 notified cases of dysentery were distributed over nineteen counties, the largest returns being those of Surrey 9 and Gloucestershire 9.

In *Scotland* the principal decreases were: measles by 182, whooping-cough 125, scarlet fever 49, acute pneumonia 38, and dysentery by 19. In Glasgow the notifications of measles and whooping-cough were 109 and 95 fewer than in the preceding week, and in Edinburgh there were 22 and 23 fewer cases respectively of measles and scarlet fever.

In *Northern Ireland* the slight rise in the measles figure was due to the experience of the city of Belfast, where all the cases notified were.

Tuberculosis

The numbers of cases of tuberculosis notified in England and Wales together, and in Wales alone, in 1938, 1941, and 1942, and the percentage increases or decreases in age groups, are as follows:

Number of Cases Notified

Year	ENGLAND AND WALES			WALES		
	Pulmonary	Non-pulmonary	Total	Pulmonary	Non-pulmonary	Total
1938 ..	43 205	14,888	58,093	3,096	1,129	4,225
1941 ..	46,256	13,720	59,976	3,286	1,107	4,393
1942 ..	46,734	13,998	60,732	3,262	1,025	4,287

Notifications in Age Groups

ENGLAND AND WALES

Ages	0–	1–	5–	10–	15–	20–	25–	35–	45–	55–	65–	Total
1938	439	2,852	4,434	3,543	6,823	7,715	12,417	8,022	5,997	4,092	1,759	58,093
1941	452	2,921	3,553	2,918	7,132	8,197	13,240	8,932	6,301	4,378	1,952	59,976
1942	372	2,783	3,729	3,032	7,129	9,133	12,944	9,179	6,160	4,336	1,935	60,732
% increase or decrease in 1942 compared with:												
1938	−15	−24	−16	−14	+4	+18	+4	+14	+3	+6	+10	+5
1941	−18	− 5	+ 5	+ 4	—	+11	−2	+3	−2	−1	− 1	+1

WALES

Ages	0–	1–	5–	10–	15–	20–	25–	35–	45–	55–	65–	Total
1938	20	208	254	293	581	631	903	535	406	266	128	4,225
1941	18	205	259	253	645	684	1,006	625	357	237	104	4,393
1942	19	186	248	206	589	706	950	629	355	289	110	4,287
% increase or decrease in 1942 compared with:												
1938	−5	−10	−2	−30	+1	+12	+5	+18	−12	+ 9	−14	+1
1941	+6	− 9	−4	−18	−9	+ 3	−5	+ 1	—	+22	+ 6	−2

The increased incidence in 1941 and 1942 affected the adult population, while the notifications at ages under 15 were less than in 1938. In England and Wales an increase occurred in each age group above age 15 during 1941 compared with 1938. The largest increases were in the age groups 20–25 and 35–45, and in 1942 a further increase was recorded in these age groups while a slight decline occurred at all other ages, but the incidence remained during 1942 above the 1938 level for all ages over 15.

The Week Ending May 1

The notifications of infectious diseases in England and Wales during the week included the following: scarlet fever 1,683, whooping-cough 1,640, diphtheria 667, measles 13,104, acute pneumonia 906, cerebrospinal fever 86, dysentery 135, paratyphoid 2, typhoid 16.

Medical News

The annual meeting of the Royal Medical Benevolent Fund will be held at 3 p.m. on Tuesday, May 25, at the Royal Society of Medicine, 1, Wimpole Street, W., when the financial statement for the year 1942 will be presented and the officers, committee, and honorary auditors elected for the current year.

A meeting of the Tuberculosis Association will be held at Manson House, 26, Portland Place, W., on Friday, May 21, at 4 p.m., for a discussion on "Wartime Diet and the Tuberculous Patient."

A lecture arranged by the British Institute of Philosophy, entitled "Freewill, Determinism, and Rational Choice," will be given by Mr. D. G. C. Macnabb of Oxford at University Hall, 14, Gordon Square, W.C.1, on May 21 at 5 p.m. Cards of admission may be obtained free of charge from the Director of Studies at University Hall.

A meeting of the Council of the Medical Superintendents' Society will be held at the Midland Hotel, Derby, on Sunday, May 23, at 2 p.m.

The London Association of the Medical Women's Federation will hold a clinical meeting at the Royal Free Hospital on Saturday, May 22, when diseases of children will be demonstrated.

A week-end course on factory medical services and industrial diseases will be held in the medical school of Manchester University on May 22 and 23. "Nutrition of the Industrial Worker in War-time," speaker Dr. E. H. Capel, is the subject for the Saturday afternoon. On Sunday morning Prof. Daniel Dougal and Dr. Joan Harwood will speak on "Gynaecological Conditions affecting Industry," and in the afternoon Mr. W. Sayle Creer will discuss "Food Faults related to Form and Function." The fee for the course is one guinea.

At a meeting held in London on May 4, sixty practitioners being present with Lord Horder in the chair, the British Association of Physical Medicine was formally constituted. The members of the inquiry committee were elected as the nucleus of the council of the association. Practitioners interested in the new association are invited to nominate a name or names of registered medical men or women to serve as additional members of the council. These names should be sent to the acting Secretary, Sir Frank Fox, 106, Finchley Road, N.W.3, before May 20. They will be submitted to a ballot at the next meeting of the association, to be held at 11, Chandos Street, W., at 2.30 p.m. on Tuesday, May 25.

A Women's Advisory Council of the Nuffield Provincial Hospitals Trust has been formed, the members of which are associated with almoning, domestic science, the general public, health visiting and district nursing, industrial psychology, local authorities, mental health, nutrition, recruitment, rehabilitation, and social service. The terms of reference include assisting the Trustees in the organization and development of medical nursing, welfare and health services, especially in relation to the co-ordination of hospital services, of social medicine, and of such other matters as will further the interests of women. Mrs. Montagu Norman is to be chairman and Miss Frances Goodall, S.R.N., General Secretary of the Royal College of Nursing, honorary secretary.

The Capetown Postgraduate Medical Association, whose headquarters are at the University of Capetown Medical School, Mowbray, C.P., South Africa, now publishes ten times a year a journal bearing the title *Clinical Proceedings* (price 2s. 6d.).

On May 8 Dr. F. Parkes Weber celebrated a double anniversary: the half-centenary of his election to the honorary staff of the German Hospital, of which he is still senior physician, and his eightieth birthday.

On May 3 President Roosevelt appointed Brigadier-General Norman T. Kirk to be Surgeon-General of the U.S. Army in succession to Major-General James C. Magee.

Over eighty local authorities have passed resolutions supporting proposals for the prevention of smoke in post-war building that have been made by the National Smoke Abatement Society (94, Manor Green Road, Epsom, Surrey). The list, published in the current number of *Smokeless Air*, includes most of the larger cities and boroughs and represents over ten millions of the urban population.

A hundred men are now carrying out the most intensive mosquito control and eradication campaign ever launched by the Brisbane City Council. They are spraying creeks and watercourses, draining low land, and seeking particularly the haunts of mosquitoes carrying dengue.

The Marie Denny Memorial Trustees have made a gift of the value of £37,000 to the Queen Elizabeth Hospital for Children, Hackney Road.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.) Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Precautions in Haemophilia

Q.—*What is the modern treatment for haemophilia? What precautions should a general practitioner take before performing a minor operation or advising, for example, tooth extraction?*

A.—There is no generally accepted maintenance treatment for haemophilia. Claims for the value of extracts of egg white or plant extracts must be regarded as unconfirmed. The patient's blood group should be determined before operation, and if he is anaemic a pint or more of fresh blood should be given shortly before or during operation. After operation it is best to wait and see, for bleeding is neither inevitable nor predictable. If the patient bleeds after operation, apply Russell-viper venom (Boots or B.W. & Co.) or thrombin (Maw) locally, taking care to avoid undue pressure or trauma, and transfuse as often as necessary to relieve anaemia and reduce the coagulation time.

Position of the Grey Matter

Q.—*Why is the grey matter on the outside of the cerebrum and on the inside in the spinal cord?*

A.—In primitive animals the grey matter of the central nervous system was inside and the white matter outside, as it is in the spinal cord of man to-day. Such an arrangement, however, did not allow for an expansion of the nervous system to any great degree. Attempts have been made during the course of evolution to expand the central nervous system by increasing the amount of central grey matter—e.g., the corpus striatum in birds. But there is clearly a limit to expansion by this means. It is for this reason that the grey matter is developed on the outside of the cerebrum. In order to reduce the length and volume of nerve fibres to a minimum, the cerebral cortex, by virtue of the vast number of connexions which it makes, must remain a thin layer. In order that the cortex may nevertheless expand, convolutions have appeared and thus made it possible for the grey matter to expand to an enormous extent without a corresponding increase in the volume of the brain.

Counting Spermatozoa

Q.—*I have been wanting to perform my own spermatozoa counts when investigating cases of sterility. I have been unable to find among my books of reference any satisfactory account of the manner in which one should conduct an examination of a condom specimen. Would you be kind enough to give me the name of a book which gives the details of this examination?*

A.—The most complete account of modern semen analysis will be found in *Human Sterility and Impaired Fertility*, by Lane-Roberts, Sharman, Kenneth Walker, and Wiesner. Some of the methods employed require special equipment, but the counting of spermatozoa and the examination of their morphology can be carried out without this.

Lingual Ulcers

Q.—*I have a female patient, aged 33 years, who has been troubled with ulcers on the tongue and on the mucous membrane of the mouth. She has had these for four years. They vary from very small ones about 1/8 of an inch in diameter to deep, ugly, excavating ones half an inch in diameter. They are very painful. She has four artificial teeth and wears a small dental plate. The teeth have been checked by a dentist and by x-ray examination. The Wassermann reaction is negative. Urine is normal. In fact everything appears normal. I have given her the following treatment: (1) small doses of novarsenobillon intravenously; (2) courses of sulphapyridine and sulphanilamide; (3) courses of stock staph. and strep. vaccine;*

(4) courses of calcium both intravenously and intramuscularly; (5) the usual local treatment. All have failed miserably. Any suggestions will be welcomed.

A.—The diagnosis of persistent ulcers of the tongue in the absence of evidence of neoplasm or syphilis is often difficult. In the present case the duration excludes the former and the Wassermann reaction the latter. There are three possibilities, however, which require further investigation—tuberculosis, vitamin deficiency, and electrolytic effect from dissimilar metals in the denture and any tooth stoppings. Tuberculosis is best confirmed by biopsy, but search of the stools (or stomach washings) for the organism may be of help. The distribution of the ulcers outside as well as on the tongue would agree with a vitamin deficiency, particularly, of course, the B factors, while the dentist should be able to express an opinion as to the likelihood of electrolytic action

Immunization against Pertussis

Q.—*In your review of "Preventive Inoculation," by W. Powell Phillips and C. Woodroffe Anderson (March 20, p. 353), you say, "It is pleasing to note this advocacy of immunization against pertussis; unfortunately the recent work of Bell on the efficacy of two doses of pertussis vaccine at a month's interval instead of 4 to 5 weekly injections came too late for inclusion in the text" There seems to be a good deal of controversy about the best method to adopt. I should be greatly helped if you could kindly tell me which is the work of Bell in which I can see his conclusions on this subject.*

A.—Most of the field trials on the prophylaxis of pertussis by specific vaccines have been done in the U.S.A., where the usual practice is to give 3, 4, or 5 weekly injections of smooth-phase vaccine (10,000–20,000 million organisms per c.cm.) totalling 80,000–100,000 million organisms. To avoid frequent injections of such big doses, which for large-scale immunization introduce difficulties in both production and administration, Bell[1] carried out a well-planned and well-controlled experiment in Norfolk, Virginia, using two 1-c.cm. doses (10,000 million organisms per c.cm.) of alum-precipitated vaccine at one month's interval. Very few children had any systematic reaction. There was some local tenderness and stiffness, but if the vaccine was not injected too superficially the firm nodule which usually developed was not noticed by the parents. The results were similar to those obtained with more frequent and larger doses. In the period of 34 months after vaccination 11.2% and 9.4% of two different age groups developed pertussis, compared with 39.1% and 29.7% among control uninoculated children. As usually happens, pertussis in a vaccinated child was milder and of shorter duration than the attack in uninoculated children. Since then Kendrick[2] has carried out comparative tests with plain and alum-precipitated vaccines, giving three 10,000-million doses of each at intervals of one week between the first and second doses and four weeks between the second and third doses, and she found no significant difference in the protective value of the two vaccines.

Diphtheria toxoid and pertussis vaccine may be combined without any inhibitory effect on the immunizing property of either antigen. It must be remembered, however, that pertussis has an earlier age incidence than diphtheria; in fact, about half the deaths from pertussis occur in the first year of life, so that specific prophylaxis should be begun at three to six months of age.

LETTERS, NOTES, ETC.

The Imperial Institute's Jubilee

On May 10, 1893, one of the least publicized but most useful national institutions in Britain was opened. It was the Imperial Institute in South Kensington, and ever since Queen Victoria performed the ceremony the Institute has carried on with the work for which it was founded. Designed as a shop window and show room in which could be exhibited all the wealth of raw materials that the British Empire can provide, the Institute also had two other functions which it has admirably performed during its 50 years of life. In the laboratories a scientific staff examines samples of minerals and plant and animal products which are submitted from all over the Empire with a view to their being put to commercial use. Not long ago the Colonial Office was anxious to have an assessment made of the nutritional properties of several native foodstuffs grown in Nyasaland; the experts in South Kensington were able to provide the answer. In the plant and animal products department oils, oil seeds, gums, fibres, insecticides, and other materials from all over the Empire can be scientifically examined and their use decided; and the same type of work is being carried out on the Empire's mineral resources in the minerals department. For example, wild rubbers found in Africa are being tested for elasticity and durability—it is hoped that they may help to replace the supplies of cultivated rubber lost in Malaya. Further, the Institute sends films and lecturers to schools and discussion groups all over Britain.

Malignant Tertian Malaria

Dr. RICHARD FAWCITT (Ulverston) writes: I have read with interest an account of a case of malignant tertian malaria by Drs. W. L. Anderson and D. B. Bradshaw (April 24, p. 508). I should like to draw attention to the fact that a number of cases were treated at the Albert Dock Hospital in the summer and early autumn of 1940. These cases came from a ship travelling to England by the West African route. My son, Fl. Lieut. J. B. Fawcitt, now serving abroad, was at that time acting as house-physician at the hospital, and, by the kind permission of Sir Philip Manson-Bahr, published an article recording some of the cases in the *London Hospital Gazette* (1940, **44**, No. 1, 9) under the heading of "Subtertian Malaria at the Albert Dock Hospital." Furthermore, he recorded a case in conjunction with A. H. Walters under the title of "Acute Malignant Tertian Malaria: Treatment aided by Reconstituted Serum" in the *British Medical Journal* of Jan. 4, 1941 (p. 14). I trust that these references may be helpful.

Cramp in Arteriosclerosis: A Cure

Dr. J. W. J. WILLCOX (Glastonbury) writes: The one treatment which will cure most cases of cramp at night associated with arteriosclerosis is 3 gr. of quinine sulphate at bedtime. I have not known it fail in any case during the past 3 years, and I can produce 4 patients at the present time who find it infallible. Its use for this purpose is supported by the literature on the subject, to which I am indebted for its introduction, but I confess that my search for a cure extended over 25 years.

⁂ Under an order, which came into force on Jan. 5 last, quinine and its salts may not be prescribed except as antimalarial drugs.—ED., *B M J.*

Supply of Occupational Therapists

Dr. ELIZABETH CASSON writes: May I be allowed to correct an error in the article on rehabilitation in civilian hospitals (April 10, p. 454). It is stated that the sources of supply of masseuses and occupational therapists are the Chartered Society and Dorset House School respectively. "Dorset House School" should read "The Association of Occupational Therapists." The profession is young and therefore small, but it has organized itself well, and though the Dorset House School has been privileged to supply a considerable number of the personnel required for the E.M.S. hospitals, it is only one of several schools whose pupils take the Association examination.

External Application of Opium

Dr. D. PRIESTLEY SMITH (Birmingham) writes: There must be many who can confirm Dr. J. McLaren's observations (March 20, p. 370) that opium and its derivatives do take effect through the skin. It was common knowledge to our medical forefathers. Here is a striking example which anyone can verify: Dissolve two grains of morphine in a drachm of oleic acid, and, with the finger-tip, dab it lightly on the painful area in a case of herpes zoster ophthalmicus. In ten minutes you will find the patient's pain relieved and your finger-tip numb. I do not know of any other treatment that gives the patient so much relief in this condition. Those who say that opium preparations applied externally are useless state what is simply not true. The men of former generations knew better.

"Scientific" or "Unlimited" Freedom ?

Dr. DONALD M. O'CONNOR (Brenchley, Kent) writes: The spiritual descendants of the courtiers of King Canute who belittle all existing public medical services and attempt to denigrate any which are suggested for the future exhibit an amazing complacency with the present state of our affairs. Their latest war-cry is a demand for "scientific freedom." During recent years a great part of the profession has exercised its scientific freedom to abstain from learning the indications for the use of sulphapyridine, and to refrain from ascertaining whether these existed in any given case, so that this potently toxic drug has been lavishly administered for any and every febrile condition, and we have arrived at a state of affairs when nearly every mother of a pyrexial child asks on one's first visit, "Aren't you going to give M & B, doctor?" Unlimited freedom, whether it can be dubbed "scientific" or not, has its dangers.

Disclaimer

Dr. EUSTACE AKWEI of Accra, Gold Coast, West Africa, wishes to state that he has no connexion of any kind with Lieut. Eustace Alar Akwei, R.A.M.C., who was referred to in the London *Evening News* of Nov. 25, 1942, under the heading "African posed as Bachelor of Surgery."

Corrigendum

In the leading article on "Medical Applications of the Cyclotron" (May 1) the identity of the Lawrence brothers was confused. The work referred to in column 1 of page 543 is that of E. O. Lawrence (Nobel prizeman) and not J. H. as mentioned in line 11. J. H. Lawrence's work is that described in the middle of column 1 of page 544.

LONDON SATURDAY MAY 22 1943

INVESTIGATIONS DURING AN OUTBREAK OF BULLOUS IMPETIGO NEONATORUM

BY

T. H. C. BENIANS, F.R.C.S.

Pathologist to the North Middlesex County Hospital and the Prince of Wales's General Hospital

WITH THE TECHNICAL ASSISTANCE OF

J. WEBSTER and A. G. NEWMAN

Outbreaks of impetigo neonatorum apparently due to staphylococcal infection were undoubtedly much more frequent than usual during the autumn and winter of 1941, more especially in maternity hospitals and homes. It is possible that staphylococcal infections in general were increased, as is shown in the following comparative figures of in-patients operated on in a large general hospital in London.

	Oct., 1940, to March, 1941	Oct., 1941, to March, 1942
Carbuncle	6	15
Mammary abscess	11	19

The outbreak affected three maternity wards, and the main inquiry covers the four months Nov., 1941, to Feb., 1942. The three wards are on different floors of the same block, each with its own nursery, labour ward, accommodation, and staff complete. The nursing staff mix in a general way when off duty, and more closely at lectures twice weekly. Cases affected during this period number 162, though this figure includes many very mild cases. There were no deaths.

Course of the Epidemic

For many years there have been occasional cases of staphylococcal conjunctivitis in the maternity wards and rarer isolated cases of mild impetigo. In October cases of impetigo increased, and in November there was an acute outbreak. The case rate was highest during November and December, and the severity of the condition at this time was marked clinically by many cases showing large areas of small bullae which rapidly suppurated and which were associated with a papulo-pustular rash. Occasional cases of conjunctivitis continued to occur, but they showed no obvious increase of severity. After December the case rate fell, with occasional increases, and the type became as a rule much milder, consisting of a scattered papulo-pustular rash, often of only a few red spots, though a few bullous cases still occurred.

During the following 12 months the record of infections was continued, and it was found that after the disappearance of the bullous cases the mild papular type of infection continued to occur in considerable numbers, ranging from 5 to 15% of all infants; the condition might in fact be described as endemic. In the records of the epidemic period no attempt had been made to differentiate between the papular and the bullous infection, all being sent to the septic ward as cases of impetigo of varying degrees of severity, although previous to this time mild impetigos and conjunctivitis cases had not been segregated. In the light of these later observations it seems possible that the bullous type was an entirely new epidemic infection superimposed on the endemic condition.

Particulars of the Outbreak

Clinical Appearances.—The general health did not seem to be affected in the least. In both severe and mild types the rash appeared suddenly, though in a few cases a preliminary erythema had been reported; then red papules, and clear blisters which rapidly became opaque and suppurated. In severer cases the bullae were close-packed. Sometimes strikingly bilateral groups on the cheeks, neck, or inner sides of the thighs were seen. The bullous lesions were very superficial; they dried up, exfoliated, and left a smooth epithelial surface. No scarring resulted. Almost the whole of the rash "came out" at once, and there was very seldom any continuation of the process after the first two or three days, though during that time spots might continue to come out under the gentian violet paint. Recurrence while the baby remained in the "septic" nursery was not seen, though an exception to this will be referred to later. In the case of the bullae the actual site of infection was not clear, but the papular type of rash appeared to be a follicular infection; only one case was seen in which the palmar surface of the hands was affected. There were no deaths and no opportunity for a biopsy. At the height of the epidemic the bulk of the lesions were of bullous type; as the case rate fell the lesions became almost entirely papular and much more sparse, many cases having only an occasional papule.

Site of Lesions.—An analysis of 40 cases showed the favourite sites of the lesions to be: face and neck, 14; conjunctivae, 8, abdomen, 5; scalp, 4; thighs (inner sides), 4. Chest and back were rarely affected, and eyelids, nose, ears, feet, and hands not at all. Several cases affecting the eyelids (blepharitis), one in the temporal region, one on the palmar surface of the hands, and several on the margins of the axilla have since been noted. In spite of the fact that practically all of these infants were carriers of *Staph. aureus* in the nares, no instance of real infection of this area or the adjacent upper lip was seen.

The *incubation period*, or rather the average age at onset, was 9 days (estimated from a series of 30 cases). The oldest patient was 22 days, and the youngest in which a real infection was seen was 2 days. Many cases, of course, were discharged about the 10th to 14th day, and may have developed a rash later, though inquiries in the casualty department did not suggest this.

Infection by Direct Contact.—Skin infection of the *mothers* either before or after onset in the baby was not noted, at any rate not with a similar type of lesion. There was one exception. The mother of an infected child had a breast abscess (subsequently bilateral). Within a day or two after incision a sharp belt of small superficial purulent bullae appeared below the breast from the axillary fold to the midline. The condition did not suggest herpes, and it cleared up quickly. The other breast was subsequently opened and drained, but, except for a single spot, the rash did not recur. A vertical band of skin below the breast had been painted prophylactically with gentian violet; the spot occurred in the middle of this. Of the *nursing staff* who handled the infected babies one sister early in the epidemic developed a perionychia. She left hospital before it was opened. It was presumably a staphylococcal infection, though not necessarily derived from her charges. Contact infection of nurses in the maternity or septic nursery was not observed. Among *infants* the direct infection of a healthy child from an infected one would appear to be an unusual event even given the most

4298

favourable circumstances. The infected infants were isolated in a "septic" nursery, and their mothers were removed to the adjacent ward. Into this ward were also taken mothers who themselves had infective lesions, such as mammary abscess, and when this happened their infants, though quite healthy, went into the septic nursery. In five instances during the epidemic healthy infants were kept in this nursery mostly for several weeks. None of these infants developed an impetigo, although one of them had a single papule which rapidly cleared up. The nurses did not wash between cases, and each infant took its turn for changing with the rest on the same ward table. The infective agent must have been easily available, and we can only suppose that its infectivity was not high or that the appropriate susceptibility was not present in these five cases. In one instance pus containing an abundance of staphylococci was taken from a fresh lesion of the trunk and painted on an area of clean skin two inches below the infected patch; no infection resulted.

The Infective Agent.—In the early severe bullous types of infection a streptococcus was suspected, but this organism was not found in careful culture on specific media. Diplococci were present scantily in films from the clear fluid of the early bullae: later, frank pus and staphylococci were seen. In cultures, whether from infected eyes, bullae, or pustules, the only organism obtained was the *Staph. aureus*, and we have assumed this to be the infective agent. (In a few of the later mild papular cases a white staphylococcus was grown.) An organism with the morphological and cultural characters of *Staph. aureus* can be obtained from many sources, and though many harmless varieties or strains may be presumed to exist there is at present no certain way of identifying a pathogenic strain apart from isolating it from a lesion.

Virulence and Infectivity.—It is a well-established fact in both experimental and epidemiological research that an organism passed from case to case increases for a time in pathogenicity and in infectivity corresponding with an increase in the case rate and the severity of the disease. An epidemic fades out in part by a loss of these characters in the infective agent, partly by a development of immunity in the population (many of whom may become carriers), and partly for lack of suitable material to infect. In this epidemic or outbreak the case rate and virulence (judged by appearances, for there was no mortality) were certainly high at the same time and declined together. We know that the epidemic did not abate for lack of suitable pabulum, since this was renewed daily in the form of newborn babies. We might attribute an increased case rate alone to some sudden access of infected fomites such as insanitary laundering, but where the severity rises and then falls with the case rate on a constant basis of infectable population we must assume some change in the attributes of the infecting organism, probably by passage. This does not necessarily mean that the infants were infected directly from each other—there is, as already shown, little evidence in support of such a direct transfer. Although the simple carrying of an organism on a moist mucous membrane is not likely to exalt its virulence, it is possible that this change was taking place as a result of actual infection, probably in the nares of a carrier or carriers. Since three separate wards were affected at once we should have to assume at least one basic source of infection and a number of other persons carrying the virulent organism.

Another explanation of the apparent exaltation of virulence, as pointed out earlier here, is that an entirely new infection was superimposed and led to the bullous lesions. In favour of this view is the fact that the bullous cases seemed to occur quite suddenly, although they faded out more slowly and with a decreasing severity.

An attempt was made during the epidemic to differentiate between the infecting agent of the bullous and the papular types, but by such means as we used no characteristic difference was found. Serological typing was not available.

Where the Organism is Harboured

Nasal Carriers.—In the anterior inch of the nares where the skin is squamous, moist, and slightly alkaline, a carrier condition is apt to develop. In our series, judging from a few cases in which additional cultures were taken from inside the nasal passages with a speculum, the organisms were limited to the anterior part. Carriers of *Staph. aureus* in this position were common among the doctors and maternity nurses; as many as 85% of the latter were carriers at one time. The carrier rate among the nursing staff was followed at approximately fortnightly intervals for some 6 months. It was a somewhat uncertain procedure, depending on the development of a golden colour in the colonies after 24 hours in the incubator and a further 24 hours on the bench. As every infection cultured at this time produced a bright golden colony we accepted this as the criterion. The correlation between the case rate and the carrier rate was not a very close one. The latter reached its highest point (85%) towards the end of the most severe part of the outbreak—i.e., the beginning of January—but it was still at 70% at the end of February, when the severe bullous cases had practically ceased; it stood at 50% in April, and was down to 25% in June.

Several heavy carriers of *Staph. aureus* were present in each of the wards throughout the whole period of observation. It seems probable that this wholesale carrier state was related to deficient ventilation during the long periods of black-out. The strains isolated from carriers were in all cases coagulase-positive, and though it is not to be supposed that all were capable of causing infection it is reasonable to suppose that some were. During April and May, when the numbers were declining, some *Staph. aureus* carriers began to show colonies of *Staph. albus*; these were coagulase-negative, while the associated *Staph. aureus* remained positive.

During the winter months the carrier condition was obviously widespread; about 30% of the women admitted for labour, and nearly 100% of babies 10 days old in our nurseries, were carriers. A children's ward at the other end of the hospital showed at this time that 50% of the nurses were carriers, as were 30% of the children under 5 years.

The presence of cocci in very large numbers in the nares of a carrier is not usually associated with any obvious sign of inflammation; but a few cases of sore nares with folliculitis are found, and it is possible that these are the originators of the infection. The organisms carried are in most cases presumably derived from the air; they must, however, have a special affinity for such a locus, since cultures from the air of the wards showed that various forms of *Staph. albus* and pale staphylococci were the predominant organisms, and that *Staph. aureus* is relatively rare even in rooms inhabited by carrier nurses and infected babies. *Staph. aureus* may also be present in the throat, though much more rarely than in the nose (in our series, 5 to 15%); from these latter cases droplet infection might of course take place. Cultures from the nasopharynx were not carried out.

Dissemination.—Droplet-spread from the nose must be rare: even in sneezing almost all the droplets come through the mouth. Tests taken by shaking the used but apparently clean and dry handkerchief of a carrier over a culture plate, however, showed the dissemination of hundreds of viable organisms similar to those present in the carrier's nares, and it seems more than probable that it is mainly in this way that the bacteria get into the air and spread from one person to another. Yet cultures from the air of the wards during the epidemic did not show *Staph. aureus* in large numbers. On 3-in. culture plates exposed for half an hour during bed-making, among hundreds of colonies—mostly skin saprophytes such as *Staph. albus*, skin diphtheroids, and sarcinae—six colonies of *Staph. aureus* were the maximum found. Again, on fomites such as door-handles, light switches, and so on, a real *Staph. aureus* was hardly ever found, though paler yellow varieties and *Staph. albus* occurred.

On the other hand, finger-prints after handling a carrier's handkerchief showed a considerable number of the infecting organisms. When gloves were worn and the handkerchief was handled, organisms in the finger-prints were far fewer, and when the gloves had been lightly powdered with french chalk the growth derived from handling the handkerchief was practically negligible. Ward dust as such was not investigated. A good deal of work has been done on this subject by various people, and if the bacteria are present in the air it may be taken for granted that the floors, window-ledges, and black-out blinds have not escaped. Quite early in the epidemic *Staph.*

aureus was found in small numbers in the ward soap used for washing the babies, and from then on soap was completely interdicted and the infants rubbed with oil of arachis.

Implantation of Infection

The Skin of the Newborn.—The skin of the newborn does not show very marked differences from that of the adult. In a section from the neck the patulous funnel-shaped hair follicles appear to be wider than those of the adult in the same area and more closely crowded. There are fewer layers of epithelium, and at the base of the funnel, where the sebaceous glands open, the epithelium in infants may consist of only one layer of flattened cells. The sweat-gland orifices also show in the infant's skin as definite pits leading down to the sweat ducts, and may equally well be the seat of infection. In the one case of purulent bullae observed on the hands no doubt infection did take place by this route. These are definitely weak spots in the body covering, as well as ones likely from their shape to harbour infective organisms. It might well be that the implantation of bacteria of quite low infectivity and virulence in such sites would set up an infection.

Time of Implantation.—An investigation was carried out to try to discover the time of implantation of the infection.

1. Swabbings were taken from the vagina and thighs of ten mothers—*Staph. aureus* was not obtained from any of these. Implantation from the vagina may be regarded as rare, though it probably does occur, and two cases are described below.

2. Swabbings were made from the skin of the babies in the nursery, on the cheeks and inner parts of the thighs. Only 5 babies were tested—on the first, third, and sixth days after birth. Cultures were also made from the nares on each occasion. *Staph. aureus* was present in the nares in two cases on the first day and in four out of the five in great abundance by the sixth day. This organism was found on the cheeks in small numbers in three cases on the first day, one case on the third day, and three cases on the sixth day. On the thighs it was found only once, and that on the third day; none of these cases was or became infected up to the time of discharge. These figures are small, but they show that *Staph. aureus* may be present, on and off, on the skin of a healthy baby almost as soon as it is put into the nursery. They also show a great preponderance of implantation on the exposed areas; and that the presence of a staphylococcus on the skin does not necessarily lead to infection. Staphylococci on the cheeks may of course well come from the infant's own nose, which harbours them from an early date, and such a strain might or might not be pathogenic; but it is a striking fact that an actual infection of the nares or adjacent upper lip has not so far been encountered.

3. An obvious point of contact for the baby's face is the mother's breast and probably hands.

In an investigation to show whether the infant was likely to be infected from the mother's milk 9 cases were examined. Cultures were made from the milk on the first, third, and sixth days of the puerperium. The milk was expressed into a tube by the nurse, after cleaning the nipple, before suckling began. The milk contained *Staph. aureus* in five cases on the first day and a further two by the sixth day. In only two was the milk found uninfected on the sixth day. One of these nine infants later developed impetigo, but it belonged to a mother whose milk had remained negative throughout the investigation. These figures again are scanty, but they tend to show that the presence of *Staph. aureus* in the milk does not usually lead to infection of the baby; nor, of course, does the presence of these organisms usually lead to an infection of the breast. Even when the mother has developed an acute mastitis, thereby showing the presence of a pathogenic strain of cocci, the infant is most unlikely to contract an impetigo, though perhaps as a rule by that time it is past the usual age for infection.

Factors aiding Infection

Abrasion.—Babies are laid usually on one side or the other, and it is likely that movement of the head on rough woollen fabrics may cause irritation. There is no proof of this beyond the fact that the sides of the face were most frequently the sites of infection. We have already seen that they are a common site of implantation, and the turning of the child might lead to the common bilateral infection. On the other hand, a child had a forceps bruise on the cheek, breaking the skin in two long lines. It later developed a severe blister rash all round the neck and occipital regions; the area with the broken skin did not become infected, though the opportunities for implantation of bacteria must have been legion. This suggests an affinity of the infecting agent for epithelial rather than the deeper dermic tissues. We see the same point in the shallow bullous lesions and absence of scarring.

Heat, Moisture, and Alkalis.—The napkin area, especially the inner sides of the thighs, while not a very common site of infection, is subject to heat, moisture, and alkalinity. This region is apt to show circumscribed areas of closely massed papules or bullae, sometimes bilateral, suggesting perhaps special facilities for a rapid local spread of infection from a small unnoticed papule. Excessive *warmth* alone does not seem to favour infection. Thus three premature babies were kept at high temperatures with hot bottles in a nursery in which infected cases occurred from time to time. Only one of these developed a single papule at the end of the third week. This would be about the ordinary incidence of infection at that time. The destructive effects of alkalis on the amino-acids of the squamous epithelium is well known, and ammonia quickly develops in a wet napkin. Such lesions as occur in the napkin area are usually on the inner side of the thighs and pubic region; they were not seen actually on the genitalia. The question has also been raised whether the alkalinity of soap did not weaken the epithelium and lead to infection, but in the cases here reviewed soap had never been used.

Identification of Types or Strains of Staphylococci

In this research we might have two aims: (1) To identify a particular organism in whatever circumstances we may find it—for instance, to trace a carrier's strain in the lesions of an infected case. In one instance we believe we have been able to do this. (2) To identify a staphylococcus as pathogenic by some other criterion than taking it from an infection. The problem lies in the similarity of strains of *Staph. aureus* from the most varied sources in their reactions with the usual biochemical tests. Some 40 cultures, including those from air, nasal carriers, impetigo lesions, and known staphylococcal infections from other sources, were compared. The tests used were coagulase, haemolysis, and the hyaluronidase (diffusion factor) reaction (McClean). Of the cultures 39 were coagulase-positive. In the case of the other tests the results were very variable.

It could be said that in our hands none of these tests bore any definite relation to proved pathogenicity in any particular culture. They were used here only with the object of correlating and identifying strains from different sources. Serological typing was not available, but even if it had been it does not follow that the antigenic structure of an organism of this sort would be a guide to its infectivity.

Some Unusual Cases

1. An infant 14 days old developed small purulent blisters in a line across the front of the proximal phalanges of both hands and on the adjacent palm and inner aspect of the thumbs. These contained a very pale staphylococcus. They were probably due to direct contact with the mother's breast or fingers. This was not confirmed.

2. Two cases became infected on the second day and showed very similar lesions. The rash was of a fine papulo-pustular type with a red base, and was spread diffusely, mainly on back and shoulders. Cultures grew a nearly white staphylococcus. In both cases vaginal swabbings from the mother produced a similarly pale staphylococcus. The maternal and infant strains in both cases were similar in appearance, and all four were coagulase-positive. No further investigations were made. It seems probable that both of these cases were vaginal infections, especially bearing in mind that these infants had not been washed since birth. Both cases cleared up entirely in a few days. One of the mothers had an unexplained puerperal pyrexia.

3. An infant developed on the third day a closely packed rash of small clear blisters limited to, and more or less covering, the area supplied by the posterior roots of the second, third, and fourth cervical nerves—that is to say, the occipital and temporal regions, including the auricles, the neck, and the upper part of chest and shoulders. Later one eyelid developed a fringe of small styes and some spots on the same cheek. The face and main part of the scalp were unaffected. Cytological examination of the blister contents in the early stage showed the presence of 75% lymphocytes and 25% polymorphonuclear leucocytes. Cocci were present in the early stages and *Staph. aureus* grew scantily. Later the bullae became frankly purulent. Scrapings of the epithelium from inside the bullae in the early stages were examined for inclusion bodies, but without success. It was thought from the disposition and cytology that a neurotropic virus might have been concerned in this case.

The very short incubation period would, however, make this improbable unless the infection had been an ante-natal one

4. The fact that infants seldom or never seem to have a recurrence of the infection after removal to the "septic" nursery has been referred to. On one occasion this did occur, and four infants cured and ready to go out showed a fresh infection simultaneously, two with conjunctivitis and two with a rash on the face. A nurse known to be a carrier of *Staph. aureus* and to suffer occasionally from folliculitis of the nares had been transferred three days previously to this ward. A comparison of her cultures with those of the strains isolated from the infants' lesions showed three of them to be closely similar, and it seems probable that the new infection was derived from her. The table below shows the similarity of the cultures of Nurse A to those from the two cases of conjunctivitis and one pustule.

Cultures from Nurse and Babies of D 1 Ward

No.	Source	Coagulase	Gelatin	Litmus Milk	Diffusing Subst., up to Dilution of	Haemolysis
1A	Nose (Nurse A)	+	Liquefied	Acid clot	1·10	+
7A	Eye (baby)	+	„	„ „	1:10	Slight +
11A	Face pustule (baby)	+	„	„ „	1.10	+
12A	Eye (baby)	+	„	„ „	Nil	Slight +

Treatment of the Epidemic

Almost inevitably in the first place the organism is derived from a human source and, by-passing the various secondary modes of distribution such as dust, air, and so on, it is at the origin we should deal with it. The infection in its milder aspects might be regarded as not dissimilar to follicular acne in the young adult, and perhaps almost any strain of staphylococcus might cause it; but the severer lesions are almost certainly derived from an active cutaneous infection, most likely a folliculitis. Such a folliculitis occurring in the anterior nares and leading to a damp nose and frequent use of the handkerchief would give rise to rapid dissemination of an organism with increased infectivity. We have so far succeeded in implicating only the one case of this sort described above, from which we think we have definitely traced some infantile infections. It may be that this not very obvious type of lesion is a frequent source of infection, and such infected carriers should be sought for carefully and excluded from the maternity wards. More obvious forms of sepsis are of course excluded as a matter of routine.

Various general measures were carried out, including closing and cleaning of wards, the use of masks by all medical and nursing staff entering the wards, the use of gloves in handling the infants, and the replacement of handkerchiefs by oiled medicated gauze for both staff and mothers. The effect of these measures, if they have had any, is by no means clear. The closure of the wards for cleaning and a few days' airing can certainly be said to have had no value in stopping the infection, which began again in a bullous form within two or three days of reopening. The use of masks for nasal carriers is probably of no value: the removal of both masks and gloves led to no increase in the number of infections. The use of gloves was replaced by dipping the "socially clean" hands in a box of french chalk before handling the uninfected infant, with the object of keeping the hands dry and interposing a barrier of powder between the hand and the infant. The medicated handkerchiefs did not come into use until the epidemic was abating, and it is not possible to say whether they have played a useful part or not. They were prepared as follows: An emulsified oil having properties similar to that suggested by Van den Ende and Thomas (1941) was prepared from the following:

Sulphonated castor oil	.. .. ..	50.0 parts
Lanette wax S.X.	.. ..	5.0 „
Cresantol-3	.. ..	2.5 „
Paraffin liq. leve	.. .. .. to	100.0 „

One part of the above was diluted to 5 parts with water before use and tinted with eosin q.s.

Six-yard rolls of absorbent gauze were immersed in the emulsion until saturated and the excess of liquid was removed by wringing; the gauze was then put in a warm place until dry. Portions of gauze about 8 in. square cut to form handkerchiefs were issued twice daily.

In the event of a really serious epidemic which could not be controlled by other methods of hygiene it might be worth while to consider approaching the problem from the other end and attempting to prevent the organism obtaining lodgment in the hair follicles of the infant. This might be possible by occluding them with a natural fatty substance, say a lanolin preparation, containing a sufficient amount of a harmless bacteriostatic substance.

The treatment of carriers with a view to sterilizing the anterior nares is not a very promising field of action so far as permanent cure is concerned. One method, bearing in mind the gradual substitution of yellow by white cocci, would be an implantation of the area with a definitely non-pathogenic staphylococcus—e.g., *Staph. epidermidis albus*. Another possible method might be the use of a suitable bacteriophage.

Summary

An epidemic of bullous impetigo neonatorum due to staphylococcus infection and extending over some months was observed in three maternity wards, and the observations continued for a further 12 months. The outbreak occurred at a period when staphylococcal infections in the district were more frequent and severe than usual There was, moreover, at this time a considerable increase in the number of cases of acute mastitis. The epidemic was preceded, accompanied, and followed by mild cases of papular impetigo and staphylococcal conjunctivitis. There were no deaths.

Nasal carriers of *Staph. aureus* among the doctors and nurses, infants, and mothers were numerous and continued so after the abatement of the epidemic. It remained uncertain whether the more severe bullous cases were due to an increase of virulence in the endemic infection or to a new infecting agent. It was thought that a folliculitis of the nares was a likely source of infection and that the organism was shaken into the air from the handkerchief. Handkerchiefs were replaced by squares of oiled medicated gauze changed twice daily for all adults in the wards.

BLOOD TRANSFUSION IN NOCTURNAL HAEMOGLOBINURIA

BY

J. V. DACIE, M.B., M.R.C.P.

Pathologist in the E.M.S.

AND

DOUGLAS FIRTH, M.D., F.R.C.P.

Senior Physician, King's College Hospital

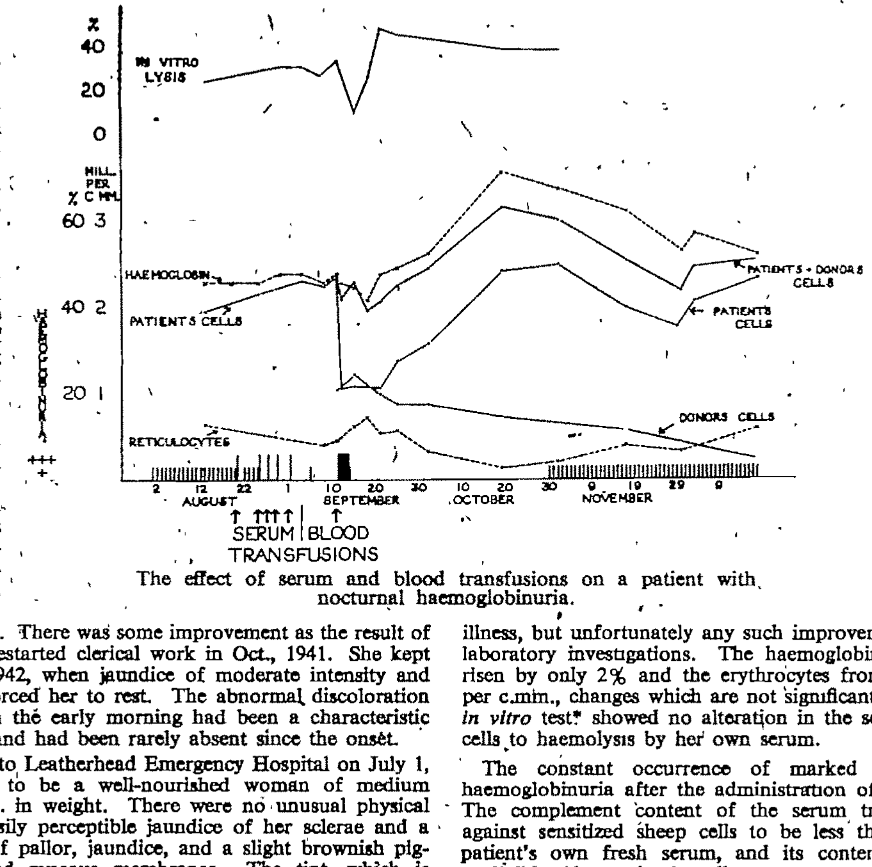
Chronic haemolytic anaemia with nocturnal haemoglobinuria (the Marchiafava-Micheli disease, or "nocturnal haemoglobinuria") is an uncommon type of haemolytic anaemia. Its clinical manifestations have been fairly well established, and accounts of about 40 cases are now available. Although the ultimate cause is unknown the mechanism of haemolysis has recently received considerable attention, and the early observations of van den Bergh (1911), Ham (1937), Dacie, Israëls, and Wilkinson (1938), and Jordan (1938) have been followed by comprehensive clinico-pathological and immunological studies by Ham (1939) and Ham and Dingle (1939). Unfortunately, this work has been as yet of little benefit to the patients. There is no specific treatment, and this disorder, although variable in course and severity, ultimately proves fatal. The known haemopoietic substances are useless, and splenectomy is ineffective and dangerous (Hamburger and Bernstein, 1936).

Transfusion has been resorted to on many occasions, and has often resulted in a severe haemolytic episode (Hamburger and Bernstein, 1936; Ham, 1939). Nevertheless, remissions after transfusion have been reported: for instance, a severe reaction in Ham's first case was followed by two weeks' freedom from haemoglobinuria, with only slight nocturnal amounts in the succeeding two weeks; and the same sequence of events followed four more transfusions in this patient. Similar observations were made on his third case. Three transfusions, each of

500 c.cm. of citrated blood, were given on alternate days to this fourth patient, who was in a severe haemolytic crisis at the time. The level of free haemoglobin in the plasma remained extremely high until 24 hours after the third transfusion. The amount of haemoglobinaemia and haemoglobinuria then fell during the next five days to the lowest levels observed in two months' observations, and the erythrocyte count eventually rose from 1,710,000 to 3,550,000 per c.mm.

It seemed possible from these observations that blood transfusion, despite its initial deleterious action, might have a more prolonged inhibitory effect upon haemolysis, perhaps owing to the presence of a naturally occurring antihaemolytic substance in the transfused blood (Josephs, 1938). It was hoped that this inhibitory effect, if substantiated, might prove to be a basis for an effective line of treatment, and with this in mind we have administered a substantial amount (2,000 c.cm. over 12 days) of stored (6-weeks-old) filtered human serum to our patient. The object of this paper is to record the results of this experiment and also of an analysis of the effects of a blood transfusion which is as detailed as wartime circumstances allow. The latter experiment was undertaken in collaboration with Dr. P. L. Mollison, who studied the survival of the transfused blood and has kindly allowed us to quote his results.

Clinical History of Case



The effect of serum and blood transfusions on a patient with nocturnal haemoglobinuria.

The patient is a woman aged 38. Her illness dates from Nov., 1940, when she noticed that the urine she passed in the mornings had become dark red in colour. At other periods during the day no abnormality of the urine was noticeable, but there was a slight but gradual deterioration in her general health; lack of energy, fatigability, and breathlessness increased imperceptibly. In April, 1941, her strength was still more impaired, and she was kept in bed at home for five weeks. The onset of pains in her legs along the distribution of the sciatic nerve resulted in her admission into another hospital, where she received treatment for sciatica. Anaemia was recognized and iron was given as treatment, but the significance of the intermittent dark urine was not appreciated and no diagnosis was made. There was some improvement as the result of rest in bed, and she restarted clerical work in Oct., 1941. She kept at work until June, 1942, when jaundice of moderate intensity and increasing weakness forced her to rest. The abnormal discoloration of the urine passed in the early morning had been a characteristic feature of her illness and had been rarely absent since the onset.

She was admitted into Leatherhead Emergency Hospital on July 1, 1942. She was seen to be a well-nourished woman of medium height and 8 st. 12 lb. in weight. There were no unusual physical stigmata except an easily perceptible jaundice of her sclerae and a curious combination of pallor, jaundice, and a slight brownish pigmentation of skin and mucous membranes. The tint, which is striking, appears to be a characteristic of the disease. Physical examination revealed no abnormalities except that the tip of the spleen was just palpable. The liver was not felt and the superficial lymph nodes showed no gross enlargement. *X*-ray examination of the kidneys did not reveal any deposits of haemosiderin.

Inspection of samples of urine showed the presence of haemoglobin at certain times of the day, characteristically in the samples passed between the early hours of the morning and 9 a.m. The urine was usually quite free at other times. The amount of blood pigment present varied; there was often enough to produce a deep port-wine discoloration.

Laboratory Investigations

Blood count on admission: erythrocytes, 2,180,000 per c.mm.; haemoglobin, 46%; C.I., 1.06; cell volume, 24.5%; m.c.v., 113 μ^3; reticulocytes, 10%; total leucocytes, 5,500 per c.mm.—polymorphs 59%, myelocytes 0.5%, metamyelocytes 3%, lymphocytes 36%, monocytes 1%, eosinophils 0.5%. Van den Bergh test, prompt reaction negative; total bilirubin, 1.4 mg. per 100 c.cm. Blood group A. Gastric residuum, achlorhydria with a moderate secretion of free acid after an alcohol meal. Bone-marrow biopsy (sternal puncture) showed active erythroblastic hyperplasia, the nucleated erythrocyte–leucocyte ratio being 1 : 2. Primary erythroblasts of all states of maturity were present, early types being relatively uncommon and haemocytoblasts still less frequent (less than 5% of total nucleated erythrocytes); normoblasts were also scarce, and there was no premature ripening of the cytoplasm of the primary erythroblasts. The leucocytes showed no noteworthy change.

Serological tests confirmed the tentative clinical diagnosis. It was demonstrated: (i) that a proportion of the patient's cells were lysed *in vitro* after 1 hour's incubation at 37° C. in autogenous fresh serum or that of normal subjects of the same group; (ii) that lysis was sensitive to changes in *p*H, and was increased by the addition of fresh guinea-pig serum from which all anti-human heterolysin had been absorbed; (iii) that the patient's cells were not lysed by guinea-pig serum in the absence of human serum; and (iv) that normal cells were not lysed by the patient's serum under any conditions. These observations are characteristic of nocturnal haemoglobinuria, and for this reason will not be elaborated further in this paper.

Transfusion of Stored Serum

After three weeks' observation 400 c.cm. of six-weeks-old filtered human serum was given intravenously in 90 minutes on the morning of Aug. 20. The patient felt none the worse, but the urine specimens during the afternoon contained much free haemoglobin. A specimen passed at 11.45 p.m. was, however, free from pigment, as were all specimens passed the following day. The regular nocturnal rhythm restarted, however, on the morning of Aug. 22, and persisted until the 25th, when a further bottle of serum was given. The immediate onset of gross haemoglobinaemia and haemoglobinuria was again followed by a period of freedom, only interrupted when further bottles of serum were given on Aug. 27 and 29 and Sept. 1. The urine remained clear until Sept. 10, except for a trace of pigment on Sept. 6. This remission was longer than any the patient could remember since the beginning of her illness, but unfortunately any such improvement was not reflected in laboratory investigations. The haemoglobin was observed to have risen by only 2% and the erythrocytes from 2,170,000 to 2,370,000 per c.mm., changes which are not significant. Moreover, a standard *in vitro* test[*] showed no alteration in the sensitivity of the patient's cells to haemolysis by her own serum.

The constant occurrence of marked haemoglobinaemia and haemoglobinuria after the administration of serum was unexpected. The complement content of the serum transfused was estimated against sensitized sheep cells to be less than 1/32 of that of the patient's own fresh serum, and its content of anti-A agglutinins negligible (the patient's cells were not agglutinated *in vitro* at a serum dilution of 1 : 2). Moreover, the transfused serum had no haemolytic activity *in vitro* on the patient's own cells in the absence of fresh serum. The reaction of the serum, which had been estimated to be slightly more acid than that of blood, was on the last two transfusions deliberately made more alkaline (*p*H 7.9) by bubbling oxygen through the serum for 10 minutes before administration. Haemolysis was not inhibited by this procedure, and it was tentatively concluded that lysis was most likely caused by the presence within the transfused serum of relatively stable components of complement (not lytic by themselves) in sufficient concentration to increase the haemolytic power of the patient's own serum.

---

[*] *In Vitro Test.*—0.1 c.cm. of a 6% suspension of washed patient's erythrocytes in 0.9% NaCl was added to 0.5 c.cm. of acidified patient's serum (serum 0.3 c.cm., N/20 HCl in 0.9% NaCl 0.15 c.cm., 0.9% NaCl 0.05 c.cm.; *p*H approximately 7.2). The amount of haemolysis produced by one hour's incubation at 37° C was estimated visually against standards.

Transfusion of Whole Blood

On the morning of Sept. 11, after the administration during the previous day and night of enough alkali to make the urine alkaline, the patient was given 500 c.cm. of a concentrated cell suspension of Group O citrate-glucose blood within 90 minutes. Before the transfusion had been quite completed symptoms suggestive of a haemolytic episode began to make their presence felt. The patient complained of a slight dizziness and backache, and a little later felt sick. These symptoms slowly progressed but never became really severe, although there was some diarrhoea and sickness during the following night. Her temperature was slightly raised, the maximum being 100.2° F. Within 24 hours of the transfusion the feeling of sickness abated and it seemed clear that the constitutional symptoms were subsiding. The patient had, however, by then become strikingly brownish-yellow in colour; the brownish tinge disappeared within a few days, but the jaundice persisted longer. Soon after the termination of the transfusion intense black urine was passed, and it continued in this state for the next 48 hours; but by the morning of Sept. 14 only a small amount of pigment was present, and the specimens passed on the 15th were clear. The urine then remained clear until Oct. 30.

The effect upon her blood is illustrated in the accompanying chart. This records (*a*) the total erythrocyte level, (*b*) the number of donor cells present, and (*c*) the level of the patient's own cells after the transfusion (*a* less *b*). The haemoglobin and reticulocyte percentages are also recorded and the presence or absence of haemoglobinuria and the results of the *in vitro* haemolysis test indicated. Study of the chart reveals several points of interest. The number of normal (donor) cells present after transfusion agreed well with expectations, there being a little more than 1 million per c.mm. This figure slowly and gradually fell, and approximately 18% of the transfused cells were still surviving 95 days after transfusion. This is essentially a normal rate of elimination (Mollison and Young, 1942). Despite the presence of 1 million per c.mm. or more of normal cells the total erythrocyte count had fallen slightly at the end of 24 hours, indicating great destruction of the patient's own cells—i.e., a fall from 2,370,000 to 1,060,000 per c.mm. The count remained at about the level of 1 million per c.mm. for 10 days or so and then rose fairly steadily, just reaching 2,500,000 per c.mm. in six weeks. The total erythrocyte count, after falling about 300,000 per c.mm., reached its pre-transfusion level in 14 days and then steadily rose to 3,180,000 per c.mm. four weeks later. The total count then slowly fell back to its pre-transfusion level of about 2,250,000 per c.mm. The reticulocyte percentage followed the erythrocyte count in an inverse manner.

The percentage lysis observed in the standard *in vitro* tests was not significantly altered by the serum transfusions; after the blood transfusion there was a period of at least a week in which the sensitivity of the cells to lysis *in vitro* was clearly diminished even after making allowance for the presence of many normal cells. This may be due to the removal from the circulation of the most sensitive cells during the haemolytic crisis precipitated by the transfusion. It is interesting to note that sensitivity to the *in vitro* tests had been fully restored, and even appeared to be slightly increased, before the onset of haemoglobinuria, and that the latter did not reappear until the erythrocyte count had regained its pre-transfusion level. No doubt the presence of haemoglobinuria depends upon the renal threshold and the amount of haemoglobin liberated into the circulation per unit time, and is therefore more likely to be found at high rather than low levels of erythrocyte counts if the proportion of cells destroyed is a constant one.

Discussion

It is generally agreed that the basis of this strange disease is an undefined abnormality of the patient's erythrocytes which causes them to haemolyse in the presence of human serum both *in vivo* and *in vitro* (see Ham and Dingle, 1939). Our observations are consistent with this hypothesis and do not support any alternative theory; in particular the possibility that the patient's erythrocytes were sensitized by the presence of an immune body or other haemolytic agent would appear to be negatived by the unimpaired survival of the transfused normal cells, unless it were assumed (without any evidence) that the hypothetical haemolytic agent was strictly autospecific.

Similarly, no evidence was forthcoming in support of the further possibility that lack of an antihaemolytic factor was responsible for the excessive breakdown of the patient's cells. Serum transfusions were without significant effect, and the ultimate rise in blood count following the blood transfusion appeared to be due to the good survival of the transfused cells. The patient's own cells did not increase significantly in numbers

Summary

A short clinical description is given of a case of chronic haemolytic anaemia with nocturnal haemoglobinuria (Marchiafava-Micheli disease).

Two litres of stored normal serum was given intravenously within 12 days; no appreciable effect on *in vivo* or *in vitro* haemolysis resulted.

A blood transfusion was followed by a severe haemolytic episode in which rather more than one-half of the patient's own erythrocytes were destroyed. The survival of the transfused blood was, however, unimpaired. The transfusion was followed by a remission from haemoglobinuria lasting 6 weeks.

The bearing of these observations on the pathogenesis of the disease is briefly discussed.

TREATMENT OF PSYCHIATRIC PATIENTS IN GENERAL HOSPITALS

A SOCIAL EXPERIMENT

BY

DALTON E. SANDS, M.R.C.P.Ed., D.P.M.

Deputy Medical Superintendent, Sutton Emergency Hospital

For centuries the peculiar symptoms of nervous and mental disorder have caused segregation to remain paramount over other aspects of treatment. This policy has been accepted, though with suspicion, by the main body of public opinion, but strongly resisted by individual patients and relatives. In Britain several thousands of patients are annually permitted to become chronic cases before specialized treatment is sought in a hospital for mental or nervous disorders because so many people, with or without good education, still regard these illnesses either as irrecoverable or to be treated conservatively at home as long as possible. Many a patient suffering from early psychosis could have avoided prolongation of illness, subsequent certification, and economic loss if either he or his relatives had not had the mistaken conception that on admission to hospital there was risk of being made worse by association with chronic patients, that active treatment scarcely existed, or that he would never be discharged. These ideas have their roots in the past, when the chief form of treatment known was to minister to the well-being of the patient on general lines as efficiently as overcrowding would allow. Under these conditions the better the quality of the personality the more likely was the individual to defer accepting hospital care, except in the most acute disorders.

Some idea of the cost of this policy may be gained from the estimation (Ebaugh, 1940) that, in the U.S.A., hospital beds are required for 100,000 patients becoming chronic annually, and in 1940 chronic psychiatric patients occupied half the total number of hospital beds. Many more are maintained in their own homes or in private nursing homes. The problem is little different in this country; for example, the London County Council in accommodating their own share of the burden require, out of a total of 72,000 beds for all types of illness, 34,000 for psychiatric patients, a large majority of the beds being for chronic cases. Another aspect is shown by Sargant and Cook (1942), who reported that 20% of the cases admitted to the medical wards of a general hospital were found to present conditions and problems primarily neuropsychiatric, regardless of the patient's initial complaint or the preliminary diagnostic impression. Heldt (1940) also places the percentage at 20 or 30, and remarks that if mention be made as well of all patients showing minor and secondary disturbances of nervous disorganization, then the figures rise still higher. Yet, with few exceptions, general hospitals refuse to admit, let alone attempt to treat, a nervous or mental patient if they know he has already been so diagnosed. In view of the incidence noted, the term "general hospital" seems scarcely a suitable one.

Hitherto the only widely organized in-patient treatment has been that afforded by the mental hospitals. In these there are six to eight doctors for 2,000 to 3,000 patients, a sufficiently high proportion if the patients are mostly chronic and in the days when the main treatment was custodial. In accommodation and classification there has been slow but steady improvement, and by legalizing voluntary admission, advocating special treatment villas for early patients, and establishing out-patient clinics, the Mental Treatment Act, 1930, brought many under treatment at an earlier stage, after the success of the Maudsley Hospital, London, and Jordanburn Hospital, Edinburgh, had emphasized the need for early voluntary accommodation. But even these hospitals have tended with time to become stigmatized as "mental," with its old-time implications, so that patients wait too long before accepting admission. Recently I have had opportunity to test the treatment of psychiatric patients in a general hospital neuropsychiatric ward, using modern methods already developed by psychiatrists, and I believe the results of this experiment allow some hope of easing this undesirable situation.

Methods

In discussing the results of a year's admissions (Table I) and the methods of this experiment, it must be stated that the 281 patients were all female, nearly all civilian, and of a selected type in that their personalities were relatively good and likely to react favourably to modern treatment. A few were admitted in attempts to influence illness of long duration by recent methods, and in others considerable investigation, involving several departments of medicine, was necessary to elucidate the complicated problems presented. The unit consisted of two adjoining wards of 30 and 16 beds housed in a block of general wards. During a minor part of the time only the small ward was available. For administrative reasons the number of beds occupied was not allowed to exceed 40, and the remaining space was used as dining accommodation for those convalescent. The wards had no side rooms, and differed in no way as regards restrictions from a general medical ward. The patients mixed with others from the medical and surgical wards at social functions and in the grounds. The medical staff consisted of two psychiatrists and very occasionally a third, all of whom had part-time duties in other parts of the hospital, including the special neurological unit. Nursing staff comprised a sister with general and psychiatric training and five nurses on each of the two daytime shifts.

TABLE I.—*Results (All Patients)*

Grade	On Discharge		Follow-up (2 to 12 Months)	
	No.	%	No.	%
Recovered	98	34·8	100	40·5
Much improved ..	41	14·5	22	8·9
Improved	93	33·3	79	32·0
No change	49	17·4	30	12·1
Relapsed	—	—	13	5·3
Died	—	—	3	1·2
Total	281	100·0	247	100·0
Total number at work ..			189	76·5

The application of treatment facilities to selected patients on exactly the same basis as for medical and surgical patients showed clearly that (*a*) many recoverable patients were failing to avail themselves of voluntary status in mental hospitals; (*b*) many were unnecessarily losing jobs and suffering economic hardship while their illness drifted into chronic invalidism or delayed recovery; (*c*) with active treatment, comparable to that afforded to medical or surgical patients in general hospitals, our patients were discharged with a combined recovered-and-improved rate of 82%, maintained with a relapse rate on follow-up of only 5.3%; and (*d*) having been so treated for an average in-patient period of six weeks, over three-quarters of them were able to return to work soon after discharge.

In particular, 70 depressive patients of various types treated by electro-convulsion therapy showed a discharge rate of 61.4% recovered, 35.6% improved or much improved, and 3% unchanged. Of 64 such patients followed up for an average of six months, 58% recovered, 33% improved or were much improved, and 9% relapsed; 85.9% were at work. There were a number of milder cases of depression in which non-specific hospital treatment was sufficient to promote recovery. Results in the small group of 28 schizophrenics treated by insulin and/or electro-convulsion therapy were in accord with the encouraging figures for larger series of patients treated by modern methods, both on discharge and follow-up. Three-quarters of these patients are now employed outside hospital. On this subject Ross *et al.* (1941) state that insulin produces an improvement significantly in excess of that obtained by any other means, and that after two years 75% of patients who were benefited had retained their improved state.

Our results (see Table I) were due to the following general scheme of treatment: Insulin comas* in early schizophrenia, electro-convulsions for depressions and some obsessional states, continuous sleep in acute anxiety neurosis, modified courses of insulin in anxiety hysteria with loss of weight, and prefrontal leucotomy for severe persistent obsessional states (which failed to react to other treatments). Psychotherapy in general or specialized form was used whenever it seemed indicated, coupled with psychological investigations under sodium amytal. Combined methods were most useful: physical methods and psychotherapy and sometimes two different physical methods have been used concurrently or successively on the same patient. (Reference has already been made to the application of these treatments in the male neurological unit of this hospital: Sargant, 1942.) In our series 9 courses of insulin coma were given, 115 of electrically induced convulsions, 28 of continuous sleep, and 94 of modified insulin; on 2 patients prefrontal leucotomy was performed, and 97 relatively specialized courses of psychotherapy were given. It has been necessary to support these measures by prompt examination of the patient, speed in instituting active treatment on the day of admission whenever possible, organized occupational therapy, and remedial exercises. By these practices such risks as those of suicide, which are inherent in treating acuter forms of psychiatric illness in an open ward, are greatly diminished, the patient becomes amenable to the efforts of the nursing staff at an early stage, and the morale of those more advanced in treatment is unimpaired. To obtain the best results one must be prepared to modify the technique and routine of treatment to suit the individual, and on discharge to give such medical recommendation as will assist resettlement in work. With the co-operation of the Ministry of Labour employment was modified in many instances to suit individual needs. In fact, general hospital psychiatric treatment has become possible because in the last three years treatment has developed sufficiently to achieve good clinical results and early control of symptoms in nearly all the numerous patients of the type reported here, without blocking beds for an unduly long period.

In all patients, duration of illness varied from one week to seventeen years, averaging one year and eleven months. In actuality, nearly three-quarters of the patients had been ill for a year or less. The average duration was somewhat distorted on account of a small group of patients admitted partly by reason of the very length of illness. Half the patients were classified as psychoses, including 111 depressives of various types and 28 schizophrenics; 38% suffered from neuroses; and other organic conditions comprised the remainder. Thirty-one psychotic and six neurotic cases were relatively acute; in only six of these was it impossible to control symptoms by treatment, and with the co-operation of the relatives they were discharged for admission to observation wards. It will therefore be noted that the most extremely disturbed patients were not nursed in our ward. The proportion discharged against advice—under 7%—seems reasonably low considering how often these patients are indecisive, suspicious, and liable to take an unreasonable course of action.

The fact that psychoses often drift on into chronicity has led to a tradition that the prognosis generally is gloomy. This view is certainly unjustified, when modern methods are employed for suitable patients. In our material the psychotics did better than the neurotics, both in their reaction to treatment and in the maintenance of improvement gained (Table II), with a negligible difference in time required in hospital. The view expressed in the *British Medical Journal* leader of Oct. 3, 1942, (p. 397) concerning the favourable outlook in the recent acute psychotics compared with the neurotics has been fully confirmed. The reason for these findings partly lies in the fairly good pre-psychotic personalities of many patients selected for admission to this ward, in their comparative youth (average age 33 years), and in the fact that they were under specialized hospital care at an earlier stage in their illness than is usually possible in mental hospitals. If it were generally realized how effective can be the speedy treatment of an early patient by the skilled use of modern methods individually applied, years of illness and invalidism could often be averted. For instance, Rivers and Bond (1941) showed that a skilled insulin therapist can raise the recovered-much-improved rate on discharge in schizophrenics as high as 79% for patients treated within the first year of illness. If insulin is given by inexperienced therapists they show that the figure only reaches 46% in the same type of patient. They state also that, irrespective of duration of illness, 63% of the more skilfully treated patients recovered or greatly improved, as compared with less than 10% in pre-insulin days. If left untreated some of our patients would undoubtedly have had to enter mental hospitals at a later date. In others the personality was sufficiently adjusted for them to stay at home at the price of long invalidism and economic dependence.

---

* Since the period under review the use of insulin therapy has increased.

Table II.—*Comparison of Results in Neurotics and Psychotics*

Diagnosis	On Discharge					Follow-up (2 to 12 Months)						
	R	MI	I	NC	Total	R	MI	I	NC	Rel	Total	At Work

R=Recovered; MI=Much improved; I=Improved; NC=No change; Rel=Relapsed.
*Average stay: Neuroses, 45·7 days; Psychoses, 47·1 days.

Commentary

This experiment in hospital procedure offers advantages for patients, the medical profession, and the administrative services. Patients and relatives appreciated active treatment in a general hospital instead of the unfamiliar mental hospital. On discharge their social readjustment and employment presented less difficulty than if associates or employers were aware of recent mental hospital care. Even the large depressive and smaller schizophrenic groups, the very nature of whose illness has sometimes precluded acceptance of early in-patient mental-hospital treatment even under voluntary status, often sought and nearly always accepted active treatment in a general hospital neuropsychiatric ward. The patients have shown that this type of ward is a most promising weapon for combating the so-called stigma of mental illness, and I believe it can hasten public acceptance of sufferers from nervous or mental disorder as sick yet frequently recoverable people as nothing has hitherto. Provision of this form of treatment offers hope of diminishing the suicide rate in early sufferers from mental disorder. In a U.S. hospital psychiatric ward there were but two suicides in nearly four years, as opposed to three in other wards. Another psychiatric ward had none in six years.

For the profession, and especially for students, these patients are a valuable source of teaching material, contrasting strongly with the standardized display of end-results, vivid in symptoms but poor in prognosis. Their study and investigation can provide a very necessary increase of research workers and clinicians skilled in both physical and psychotherapeutic methods, and can equip the young general practitioner with the psychiatric understanding required by 30 to 60% of the symptoms shown by his patients. Similar improvements can be obtained in the quality and status of the nursing staff. Psychiatry demands expert and intelligent nursing, because the safety and success of such physical methods as insulin comas or continuous narcosis depend on the efficiency of the nurse in charge.

Most general practitioners dislike certifying any of their patients or having to send them to observation wards against their wishes. Occasionally there is the threat of legal action by resentful patients or relatives. Timely use of the general hospital psychiatric ward can solve many of these problems.

The advantage of ready access to specialist opinion for securing early neuropsychiatric diagnosis has been shown by Sargant and Cook (1942), particularly with regard to shortening the patient's time in hospital and saving innumerable laboratory investigations and much maintenance expense. In this hospital such assistance has been part of the service rendered to the general medical and surgical wards in return for their advice on our patients, obtained on 94 occasions.

For administrative services there have been two main advantages: (1) At least 16 hospitals in the London area have used the psychiatric facilities afforded. Had more accommodation been possible it could easily have been filled. (2) In financial economy, compare the treatment of any early case of schizophrenia by insulin shock in an eight-weeks period at the L.C.C. peacetime general hospital rate of £3 10s. a week with the frequent care of the chronic patient at the mental hospital rate averaging £1 9s. for five years—i.e., £28 to £377. If total chronicity occurs from lack of early treatment the cost rises to £2,600 for 25 years. The potential financial saving inherent in our own and Rivers and Bond's results, noted above, is therefore particularly impressive. These economies have occurred with the use of unpretentious temporary wartime accommodation, and apart from minor adjustments no unusual or elaborate structures are required.

In a small-scale test this experiment has shown many definite advantages, but it certainly raises its own problems. For instance, to what extent can mental hospital services, at present largely organized to meet the maintenance needs of an abundance of chronic patients, be adjusted to secure the confidence of the early-recoverable patient, so that this confidence would lead to their early treatment and lessen the incidence of chronicity? In common with some mental hospitals we find modern therapeutic methods to be of much assistance in this respect.

There is no doubt that extensive reorganization of mental health facilities, already under discussion, can disperse many of the present objections. Its full realization is likely to be a matter of several years. Meanwhile, the combination of out-patient clinic, mental hospital, and general hospital neuropsychiatric unit suggests a practical basis for a more comprehensive mental health service, calculated to supply early treatment in a form acceptable to many potentially recoverable patients as well as relief to the more chronic types of illness.

Summary

Investigation has been made of 281 patients selected for psychiatric treatment in a general hospital during a year. After an average in-patient period of six weeks, over three-quarters were able to return to work, the usual length of illness having been greatly shortened and chronicity avoided in many cases. Clinical recovery and improvement on discharge (82%) was maintained on follow-up, with loss of 5% relapsed. The scheme of modern psychiatric treatment used is described.

The experiment has been discussed in relation to therapeutic, professional, financial, and other fields.

I wish to express my sincere thanks to Dr. Louis Minski, medical superintendent; and to Dr. E. T. O. Slater for most helpful criticism and advice; also to Dr. W. Sargant for advice on physical methods of treatment, and to Dr. H. J. Shorvon, Sister E. A. Gaunt Murphie, and Miss J. M. Moore for their valuable assistance.

F. W. Taylor (*J. Amer. med. Ass.*, 1942, **118,** 1196) observes that chronic ulcers of the limbs, predominantly of the legs, due to infection with a haemolytic streptococcus have received little attention. The lesion is chronic and similar to that of varicose ulceration, and is usually seen in children and young adults with no apparent vascular abnormality. The 19 cases he describes responded well to sulphanilamide by mouth.

ATROPINE GLAUCOMA

BY

J. E. MARTIN, M.B., Ch.B.

Late Senior Resident Officer, Bristol Eye Hospital

This tragic condition continues to blind many eyes. Among the most valuable of drugs used in the successful treatment of eye conditions is atropine. Yet, when contra-indicated, this drug is one of the most dangerous that can be instilled into the eye.

Before its use diagnosis is essential. A spot differential diagnosis between the more frequent conditions, such as conjunctivitis, keratitis, iritis, primary congestive glaucoma, and secondary glaucoma, can at times exercise the most experienced, and so can the differentiation between "simple" glaucoma, the eye predisposed to glaucoma, and a normal eye.

I refer to the necessity for recognizing the normal eye because "simple" glaucoma is a most insidious progressively damaging condition, simulating the normal by absence of pain or visible outward signs. It is far from being simple. When in doubt, and a dilated pupil is required, homatropine can be used with greater safety, because eserine will contract the resultant mydriasis if necessary. The action of atropine on the intra-ocular muscles is clinically irreversible (Duke-Elder, 1932-7; Parsons, 1942), and in its presence eserine is ineffective. An eye is atropinized or not, and the use of weak solutions does not give a margin of safety. Once atropinized, a period of several days may have to elapse for the effect to pass off after the use of atropine has been stopped. Much mischief may happen in this interval if a dilated pupil has been contraindicated.

It may not be out of place to revise briefly the main mechanical conditions involved.

Conditions leading to Glaucoma

The eye is a closed chamber into which aqueous is constantly being secreted by the ciliary body, and from which an equal amount of aqueous must therefore escape through the drainage system of the canal of Schlemm. This venous canal runs concentrically round and close to the apex of the drainage angle in the junction of cornea and sclera. It is separated from the aqueous of the anterior chamber by a fine filter meshwork—the ligamentum pectinatum. In drawing the accompanying sagittal diagrams irrelevant details and labelling of structures have been omitted so as to preserve clarity. These illustrations represent the normal eye with the pupil of average size. It will be seen that the lens is supported posteriorly by the more solid vitreous (Fig. 1), and that any swelling of the lens will tend to displace forward the iris as a whole. Also, if the pupil is dilated the consequent thickening of the iris bulk will encroach upon the filtration angle. The iris, ciliary body, and choroid (shown in solid black) are related developmentally and clinically. These highly vascular pigmented structures form the uvea: thus iritis, iridocyclitis, uveitis. The canal of Schlemm appears as an elongated O lying on its side, and the retina is seen on the inner surface of the choroid. The arrows (Fig. 2) indicate the main flow of aqueous from the ciliary body into the posterior chamber, then between the lens and iris and forward through the pupil into the anterior chamber to the canal of Schlemm. Posteriorly is shown the funnel-shaped scleral aperture for the optic nerve, with its anterior acute rim. It is on this sharp rim that the impact of an increased intra-ocular pressure first makes itself felt on the retinal nerve fibres as they converge, streaming in to form the optic nerve—rather like barking one's shins on a sharp-edged object.

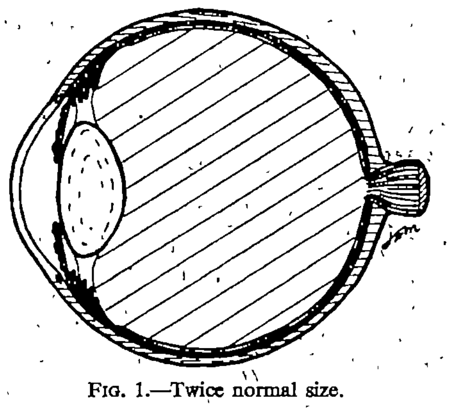

FIG. 1.—Twice normal size.

A watch-face serves well to illustrate the front view and relationship of the main structures of the anterior part of the eye. The glass cover represents the cornea, the dial the iris, and the central spindle-hole for the hands the pupil. The space between the glass and the dial is the anterior chamber. The flow of aqueous would be forward through the spindle-hole, over the dial-plate towards the numerals, and beyond these to the angle where the glass rim meets the peripheral edge of the dial. In a normal eye the balance of this flow is delicately kept and the resultant pressure within the eye, with small variations, is about 25 mm. of mercury. If, however, the drainage system is defective or becomes partially blocked, the outflow is impeded and diminished till the hydraulic-pressure head is raised above normal to overcome the resistance. This state is glaucoma.

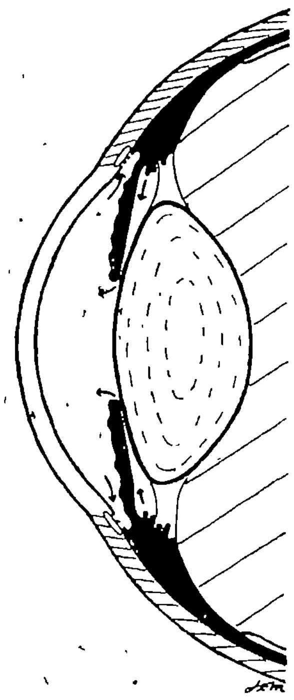

FIG. 2.—Four times normal size.

Atropine and the Drainage Outflow

Atropine paralyses the ciliary muscle and so abolishes the power of accommodation. It also prevents the sphincter muscle of the iris from receiving impulses from the third nerve, with the result that the muscle is ineffective. The pupil therefore dilates (except where synechiae prevent this).

Eserine accentuates stimuli from the third nerve to the sphincter iridis and the ciliary muscle. Under its influence the pupil contracts, the iris is stretched, and the ciliary muscle pulls on its insertion and on the root of the iris, thus tending to open the drainage angle and thereby improve the outflow of aqueous.

In mydriasis the pupil is much dilated and the iris structure is "bunched up" together and therefore thicker. In miosis the pupil is much reduced in size by the overaction of the sphincter muscle, and the iris itself is stretched fully and is at its thinnest.

For purposes of comparison let a room represent an eye. The window is the cornea, a pair of heavy curtains the iris, and the wall-paper opposite, the retina. If the curtains are drawn nearly together the small space between their edges will represent the pupil in miosis (as in the slit-like pupil of the cat). If now the curtains are pulled aside fully the "pupil" will be large; but the curtain bulk has had to go somewhere, and we find that it has "bunched up" or folded upon itself so that on the whole it has become thicker.

In the human eye the iridic curtain is circular; the iris root and the aperture edge are approximately concentric. It is this thickening or "bunching up" of the iris in mydriasis that can play the dangerous part by plugging the drainage outflow.

The lens of the eye is an epithelial structure which, within its capsule like a pea in its thin jacket, continues to grow in size throughout life. It is unable to shed its older cells, as is the case with the nails and skin. The gradually enlarging lens tends to push the root of the iris forwards, narrowing the small drainage angle between the iris and the cornea. This may be sufficiently advanced at the age of 45 to be an important factor. Also, in people with relatively small corneae the disproportion between the lens and the cornea is mechanically disadvantageous. In addition, early incipient cataract is of more frequent occurrence than might be supposed. These lens changes are associated with varying degrees of water absorption and swelling of the lens. The swelling of the lens gives rise to the important clinical sign, when noted, of progressively increasing myopia, actual or relative.

Should the pupil of an eye in which these conditions prevail individually or in concert be dilated, the "bunching up" and thickening of the iris at its root may, and probably will, sufficiently plug up the drainage outflow to induce the onset of "simple" or of acute glaucoma. If atropine was the mydriatic used the situation would be difficult even if recognized early.

When to Use Atropine

It must not be assumed that advancing age contraindicates the use of atropine. It is the condition of the eye itself, irrespective of age, that may contraindicate the drug, and special difficulties arise when more than one clinical intra-ocular condition coexist, as in the secondary glaucomas. One of my patients who has double iridocyclitis is aged 90, and I have instilled atropine into both his eyes, but not before I had amply satisfied myself that there was no predisposition to glaucoma.

It may be impossible even for those in constant practice to decide by digital means that an intra-ocular pressure is not slightly raised, and other methods and data should be relied on in the important finer variations. The digital method of judging the state of intra-ocular pressure requires special technique, and to attempt to do this with the tarsal plate of the lid interposed between the finger-tips and the eye is fatuous.

For ophthalmoscopic examination euphthalmine lamellae and B.W. euphthalmine ophthalmic "Tabloid" are efficient and safest, while for the more simple conditions requiring rest of the eye by mydriasis and cycloplegia homatropine (not homatropine and cocaine, in repeated instillations) may be sufficient. Where full mydriasis and cycloplegia are indicated atropine should be employed boldly by instillation of the solution, the solid form, or if necessary by the subconjunctival route, but not before efficient drainage of the aqueous has been proved, and never indiscriminately.

A *Supplement* to the *London Gazette*, dated May 7, announces the appointment as M.B.E. (Civil Division) of Burgess Barnett, M.R.C.S., and Capt. S. D. Sawyer, M.B., Army in Burma Reserve of Officers. The announcements state that Dr. Burgess Barnett was a member of the party which evacuated from Burma via the Chaukan Pass and was one of the last dozen men to be rescued from Tilung Hka. He elected to remain with the remnants of the party until the end, and thus secured to them the medical attention they all so sorely needed. Dr. Barnett's conduct throughout this long and difficult march over uninhabited country, in the most trying conditions of the monsoon, was worthy of the best traditions of the medical Service. Capt. Sawyer, after retreating into Manipur with the Burma Army, volunteered to remain behind in the Naga Hills in an endeavour to extricate the many thousands of refugees who were still coming out. He served during June and July with great distinction and helped many hundreds of refugees on the Tonhe–Yaripok–Imphal route. Early in September he volunteered to go out again in a final attempt to rescue those unfortunate evacuees who had been forced to spend the rains at Shinbwiyang. No other doctor was available for this duty, and he remained there until the 1,600 survivors had been brought out safely to Margherita by Dec. 5, 1942. Capt. Sawyer showed an outstanding sense of duty and self-sacrifice and saved many lives.

SPECIFICATIONS FOR DARK-ADAPTATION TESTS

BY

K. J. W. CRAIK, M.A., Ph.D.
Psychological Laboratory, Cambridge

As the question of the exact specification of the light used in adaptometers has been raised by Mr. Bishop Harman (1943), it seems opportune to emphasize that there are two aspects to this problem. The first is *standardization*, or agreement as to the size of field, form, or figure used, colour temperature of light, duration of exposure, retinal area to be tested, presence or absence of a fixation point, etc., irrespective of the physical method of obtaining these things; while the second is *calibration*, or exact measurement of the physical properties of the instrument and their accurate reproduction in copies of it.

Standardization

Regarding the first, there is as yet insufficient information on the relation between rate of adaptation, cone threshold, final rod threshold, and acuity or form sense at low illuminations to show what is the best presentation or type of test to use, either as a selection test (for picking out people with dangerously poor or strikingly good night vision) or as a vitamin-A-deficiency test. However, much work with different kinds of tests is proceeding in many parts of the country, and some work directly intended to show the relation between the results of different tests and to indicate what differences between tests are important and what are unimportant.

Calibration of Instruments

Regarding calibration, the most important characteristics to be measured are the size of field, the size of the form or figure used, if any, the colour of the light, the retinal area to be tested, and the duration of the exposure (if this is a flash, as in the Steven-Wald apparatus, or the time given to the subject for his decision in other tests). These characteristics have been accurately measured and described in most of the best work on dark adaptation—e.g., that of Hecht and his collaborators. In the Army pentagon test (Rycroft, 1942) it is specified that the translucent screens in any one instrument must all be made from the same sheet of material, and the brightness of the outside surface of the screens is measured directly with a photometer in calibrating the instruments, so that variations between one batch of sheets and another do not matter. The dark-filters used in the goggles worn by the subject are individually measured for density and are all of the same material. The brightness and angular size of the surface of the screen, as seen by the subject, are the main features on which the threshold depends. As pointed out by Dr. Yudkin (p. 633), the illumination falling on the eye does not really determine the threshold, since the same illumination may be visible (if it comes from a small bright field) or invisible (if it comes from a much larger but dimmer one). In the pentagon test arrangements are being made to check the surface brightness of the screens periodically by sending round a portable photometer. There is as yet no agreement even among photometrists as to the colour temperature of the light, which should be standardized for brightness and illumination measurements, and this introduces a serious difficulty in adaptometry, as a bluish-white and a yellow light having the same brightness at high intensities may differ threefold or more in apparent brightness when very dim. For this reason it was decided to specify the brightness of the pentagon test in terms of the brightness of the screens, the type of bulb, and the "neutral" material used for the filters; it is easier to obtain a uniform batch of a material than to get special materials made to a known spectral transmission curve and density; but as these properties are measurable it would be possible to specify the equivalent colour temperature and the brightness of the screens as seen by the subject in equivalent foot-candles or candles per square foot. It is admittedly not easy to ensure that many instruments are identical within certain limits; for instance, the small bulbs so desirable on account of their low current consumption can sometimes change a little, and instrument-making firms do not usually possess suitable equipment for calibrating such instruments. Yet it appears that such bulbs, with a good voltmeter or ammeter, provide the best light source.

I have measured the candle-power of two of the standard candles provided for the Bishop Harman test in their draught-proof lamphouse, and found that during the first 40 minutes of burning there was a gradual increase from 0.75 to 2.0 c.p., and after that a decline to 0.6 c.p. without there being evidence of anything wrong with the candle. After this the candle failed in each case to move up in its spring socket, though there was about 1¼ in. unburnt; if this escaped notice the light dropped further to 0.2 c.p. Thus the light varies over a threefold range when the instrument appears to be functioning properly, and if one does not watch the behaviour of the candle carefully a tenfold change can occur. The literature indicates twofold or threefold threshold changes as significant in vitamin A deficiency, and suggests that the individual variation in thresholds among a large population, excluding cases of retinitis pigmentosa and other pathological conditions, is about sixteenfold. Thus a twofold or threefold variation in light can be very serious for clinical purposes, and a variation as great as tenfold would invalidate the test even for rough personnel-selection purposes. An endeavour should be made to achieve about ±15% in the accuracy of night-vision tests for such work.

Conclusion

I should like to add two remarks to Major Rycroft's paper on Army night-vision testing. First, it may not have been clear that the reason for using goggles with dark filters during the test was to exclude stray light in the hut—for a blacked-out Nissen hut is by no means totally dark. Secondly, the pentagon was originally designed as a multiple or group test for examining five men simultaneously, but individual testing proved superior in practice. The attempt to make a multiple test had, however, introduced instrumental difficulties in obtaining even illumination on several panels, which need not arise in an individual test. A neutral wedge seems an almost ideal method of light control, giving a continuous logarithmic scale without appreciable change in the colour of the light, and permitting calibration of the wedge at high intensities.

A CRITIQUE OF THE BISHOP HARMAN TEST FOR NIGHT VISION

BY

JOHN YUDKIN,* M.B., Ph.D., F.I.C.

Dunn Nutritional Laboratory, University of Cambridge and Medical Research Council

IN COLLABORATION WITH

ANDREW FERGUSON

Sheffield, and Trinity Hall, Cambridge

A new apparatus for the measurement of night vision has recently been described by Bishop Harman (1941a, 1941b, 1943). It consists of 4 groups of white disks, each half an inch in diameter, mounted on a black background. Each group comprises 4, 5, 6, or 7 disks, and only one group is uncovered at a time. The illumination is provided by a standard candle 5 metres away. The subject, after 15 minutes in the dark room, is required to stand at such a distance from the disks that they can just be distinguished and counted. It was found by Bishop Harman that " the average person can count these . . . at a distance of 5 metres." A shorter distance (down to 1.5 metres) is taken to indicate poorer night vision, and a greater distance (up to 8 metres) to indicate exceptionally good night vision.

It is clear from the description of the instrument and its mode of use that the measurements which are recorded involve factors other than dark adapation. The following considerations in particular show this (see also Godding, 1941).

1. The test objects are small and close to each other, so that they are perceived mainly by the cones of the macular region. Dark adaptation, on the other hand, is much greater in the rods of the peripheral field. It might be argued that it is macular vision which is concerned with accurate vision, by night as well as by day; in fact, however, vision by night is not accurate, and is to a great extent peripheral. In using this apparatus we found that the test objects are perceived better if the observer is looking a few degrees away from them. It would appear, therefore, that to some extent rods as well as cones are used; it seems that a compromise is established between the clarity given by the cones and the better dark adaptation of the rods.

2. Subjects are tested after they have been in the dark room for 15 minutes or longer. As Bishop Harman tested many subjects at a time, some were in the dark for longer than 15 minutes. Now, dark adaptation, particularly after exposures to light of high intensity such as outdoor sunshine, continues for 30 or 35 minutes. It is the rods which are mainly concerned in this prolonged improvement, and, as we have seen in the previous section, rods are to some extent used in this test. Adaptation therefore may not be complete in 15 minutes if there has been a long exposure to bright light before the test. In view of these facts, it seems likely that subjects tested after just 15 minutes might appear to be worse than others tested later, simply because the former had not yet attained their best possible adaptation.

3. The small size and the proximity of the disks suggest that the ease with which they are seen may be greatly affected by minor errors of refraction. Bishop Harman examined all his subjects for visual acuity and confined the test to those whose acuity was normal according to his " rotary E " test. It is quite likely, however, that differences in acuity, even among these " normals," might affect the ease with which the disks are seen. In other words, the E test might not eliminate sufficiently those whose visual acuity is slightly imperfect and whose ability to see the disks is consequently limited by this factor. The statement of Bishop Harman that only one of 427 Canadian soldiers failed to pass the E test lends support to this suggestion.

4. The use of a candle as a standard of illumination has been obsolete for 40 years or more. As Walsh (1926) says, " Although once officially adopted in several countries and by various testing bodies, candles have now been entirely superseded as practical standards of light. For instance, the British Parliamentary candle, defined in the Metropolitan Gas Act of 1860, was discarded in favour of the pentane lamp by the Metropolitan Gas Referees in the *Notification* for 1898."

5. The principle of varying the amount of light entering the eye by varying the distance between the test object and the observer is highly undesirable. In the first place, it is difficult to calculate the illumination entering the eye. Bishop Harman gives the following values: at 1 metre=1/393; 2 m.=1/527; 3 m.=1/688; 4 m.=1/871; 5 m.=1/1075; 6 m.=1/1302; 7 m.=1/1550; 8 m.=1/1816 f.c. These values appear to have been derived by assuming that the disks act as mirrors, reflecting the incident light in one direction only. This is manifestly incorrect, and the disks must be taken as themselves acting as new light sources. In other words, the illumination on the eye is inversely proportional to the square of the distance of the disks from the subject, whereas Bishop Harman takes it as inversely proportional to the square of the distance of the source of light from the disks *plus* the distance of the disks from the subject. The actual illumination at the eye may be calculated thus: The intensity of light at the disk is given by the formula:

$$\text{reflection factor} \times \frac{(\text{angular size of disk})^2}{\pi} \times \text{candle-power of source.}$$

The illumination at the eye is then: $\dfrac{\text{intensity at disk}}{(\text{distance of eye from disk})^2}$.

Assuming a reflection factor at the disk of 80%, the illumination at 1 metre from the disk is 158×10^{-9} equivalent foot-candles; the illuminations at other distances are shown in the table.

Table showing Illumination at Eye at Different Distances from a Disk 1/2 in. in Diameter, illuminated by Standard Candle at 5 metres from Disk

Distance of Eye from Disk (metres)	Illumination at Eye, c.p. × 10^{-9}	
	According to Bishop Harman	Recalculated
1	2,540,000	158
2	1,900,000	39·4
3	1,450,000	17·5
4	1,150,000	9·9
5	930,000	6·3
6	770,000	4·4
7	645,000	3·2
8	550,000	2·45

The two methods of calculation give very different values, so that the illumination according to Bishop Harman varies from 16,100 times the recalculated value at 1 metre to 224,000 times at 8 metres. The value at 8 metres according to Bishop Harman is 22% of that at 1 metre, whereas it is really 1.6%.

---

* Sir Halley Stewart Fellow.

But even these data do not accurately indicate the visual effect produced on the retina. Increasing the distance of the subject from the disks not only reduces the illumination reaching him but also reduces the apparent size of the disks and the apparent distance between them. Both of these factors alter the visual effect of the illuminated test objects, and it is impossible to assess these factors. The data on illumination thus give only an approximate idea of the effect of distance in altering the visibility of the test object. All the satisfactory types of apparatus in current use are provided with a test object of constant and known angular size and an illumination of variable and known physical brightness.

The Bishop Harman Apparatus in Use

The apparatus was tested in two ways. First, since the test is performed by Bishop Harman sometimes after just 15 minutes in the dark and sometimes after a longer period, an attempt was made to determine whether, as we have suggested, improvement in response occurred subsequent to the first 15 minutes in the dark. Secondly, a comparison was made of the Bishop Harman apparatus with the Haines apparatus by testing a number of subjects on both instruments. The tests were carried out in March, 1942, on workers in a factory at Sheffield as part of a more elaborate study of dark adaptation. Only subjects whose visual acuity was 6/6 or better (Snellen cards) were examined.

Preliminary observations showed that there were several possible sources of error, the avoidance of which required careful attention. They were mainly concerned with the source of light. It was found, for example, that the standard candle occasionally burned unevenly, so that the wick became too long, with consequently a considerable increase of light. The candle is mounted in a holder with a spring to push the candle up as it burns and so keep the wick in a constant position. In practice, however, the spring may fail to do this after about one or one and a half hours, so that for the remaining 30 minutes or more the illumination decreases as the flame becomes lower in the holder. By frequent examination of the candle these errors were avoided so far as was possible.

1. Improvement of Night Vision with Time

The test was carried out on 17 subjects at intervals of 5 or 10 minutes for a total of 30 or 40 minutes after entering the dark room. During the first 15 minutes there was always considerable improvement, as shown by an increase in the distance at which the disks could be counted. In three of the subjects there was no further improvement after 15 minutes. In 10 there was a slight but definite further improvement, ranging from 0.5 to 1 metre (Fig. 1, curve A). In two individuals the improvement after the first 15 minutes was 1.5 metres, while in two further individuals it was 2 metres (Fig. 1, curve B). Quite one-third of the subjects would have been graded as "poor" by Bishop Harman at 15 minutes and as "moderate" or "good" at 30 minutes. These tests were carried out in conditions in which the previous light exposure was not very great; the men came straight from their work to be tested, and they waited in an ante-room for 5 or 10 minutes before the test was begun. The improvement after 15 minutes in the dark would presumably be greater if the test were done on subjects coming into the dark room after some time outdoors on a sunny day in summer.

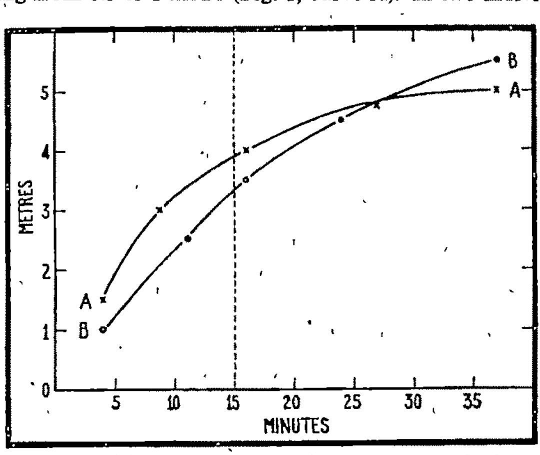

FIG. 1.—Bishop Harman test: improvement with time.

2. Comparison of the Bishop Harman and the Haines Instruments

The principle of the Haines apparatus (Haines, 1938) is the control of illumination over a wide continuous range by the use of neutral filters, together with a pair of polaroid disks. The minimum detectable illumination (threshold illumination) is determined at intervals. The instrument used in this work has been modified in certain respects and calibrated in absolute units of illumination. Its reliability was demonstrated by S. Yudkin (1941), and it has since been used by one of us in collaboration with G. W. Robertson and S. Yudkin for the measurement of the dark adaptation of upwards of 2,500 individuals (J. Yudkin, 1943; J. Yudkin *et al.*, 1943). Thirty subjects were tested with both the Bishop Harman and the Haines instruments and a comparison made of the readings obtained after at least 35 minutes in the dark. (No improvement occurred with either apparatus subsequent to this time.) If the Bishop Harman apparatus measured dark adaptation only, subjects with a high final threshold as shown by the Haines apparatus—that is, with poor dark adaptation—should give a low reading with the Bishop Harman apparatus, and conversely. In fact, however, little correlation exists between the results obtained with the two instruments (Fig. 2). (The correlation ratio, $r = 0.20$.) Some individuals with good dark adaptation (final threshold log. $\mu\mu l = 3.1$) showed a poor performance with the Bishop Harman test, and others whose dark adaptation was bad (final threshold log. $\mu\mu l > 3.5$) reacted well with the Bishop Harman test.

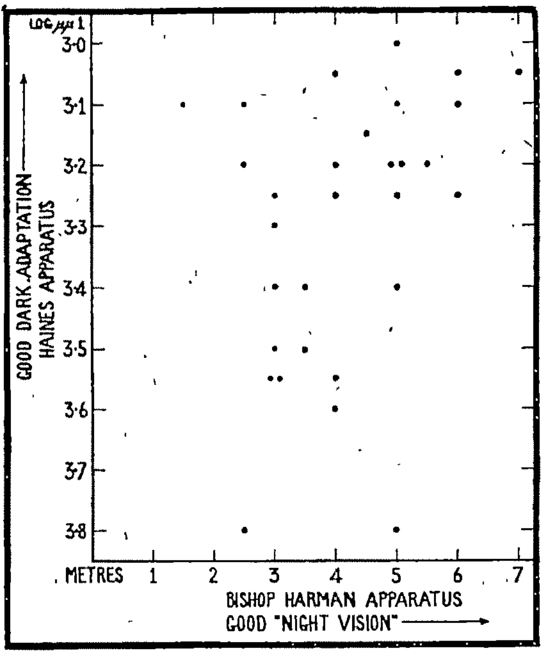

FIG. 2.—Correlation of Bishop Harman test with dark adaptation measured on the Haines instrument.

Discussion

The fact that dark adaptation is of considerable topical interest may lead to the use of unsatisfactory apparatus. This has indeed happened on several occasions: the effect has been a tendency, especially noticeable recently, to discredit a great deal of the reported results on dark adaptation, the sound as well as the unsound.

It will be seen from the findings here reported that the Bishop Harman apparatus, as suspected from theoretical considerations, does not provide a satisfactory measure of dark adaptation. Since improvement in performance occurs during the time a subject is in the dark room, dark adaptation appears to be one of the factors involved in the response to the test. On the other hand, the fact that so little correlation exists between the results recorded with the two instruments shows that other factors play a considerable part in the response to the Bishop Harman test.

Summary

An investigation of the Bishop Harman apparatus has been made with a view to determining its efficacy as an instrument for the measurement of dark adaptation. It has been shown that, besides having many theoretical objections, the test is, in practice unsatisfactory compared with well-standardized apparatus, since other factors as well as dark adaptation are involved.

We are indebted to Dr. K. J. W. Craik for much advice on the methods of calculation and interpretation of data on illumination.

Medical Memoranda

Toxic Reactions to Sulphathiazole

Identical and, I believe, rare toxic reactions to sulphathiazole in two patients in the same ward and at the same time are here recorded. The syndromes were characteristic enough to make recognition easy, once the picture had been grasped.

RECORDS OF TWO CASES

Of two patients, A and B, one had subacute bacterial endocarditis and had been running an intermittent temperature of 100° F. He had been treated for some months with sulphapyridine 1 g. q.i.d. The drug was judged to be losing its efficacy, and a change to sulphathiazole was decided upon. On Jan. 19 a course of the new drug, 2 g. q.i.d., was begun. On Jan. 28 a skin lesion was noticed. That evening the temperature rose to 104.6° F., and in the ensuing days it remained near this figure, irregularly remittent. Delirium was present. The lesions started as a number of well-separated discrete subcutaneous nodules. These quickly—in 24 hours—involved the cuticle and when fully developed presented as erythematous macular plaques. The centres appeared to be depressed owing to a single row of accurately radial pinhead vesicles at the perimeter. The whole, varying in size from a pea to a silver threepenny-piece, gave a rosette effect. Within 24 hours scabbing, without abatement of the inflammation, had begun The distribution was: forehead first, then the sides of the neck in the mastoid regions, and finally the backs of the hands and extensor aspects of the forearms. There was no pruritus.

Case B was one of traumatic thrombophlebitis of the leg with some superficial gangrene. Here, too, was a mild febrile reaction—100° to 100 4° F. To reduce possible infection, on Jan. 24 sulphathiazole in the same dosage as with A, but four-hourly, was begun. For two days the temperature fell—reaching normal on Jan. 26. Thereafter it rose by about 0.5° F. each day. On Jan. 29 several nodules appeared on the forehead. These developed as with Case A, with similar distribution and order of appearance, but the fever never exceeded 102.8° F.

The diagnosis of Case A had at first been "a shower of emboli," and, in fact, on the last day the dosage of the drug was increased to 2 g. four-hourly. Then the striking identity of distribution and sequence in the two cases was observed. The lesions were carefully compared, and were found to tally in every respect. A common infection was next considered, but this seemed improbable. The two lay in separate and reasonably distant rooms in a ward of some 35 beds. The chances of conveyance were fairly remote. Finally the drug was considered, and on the evening of Feb. 2 it was discontinued in both cases. On the following morning A's temperature was normal; B's continued to fall during the next week, reaching normality on the seventh day. (A was taking fluids well; B rather poorly.) In both cases the skin lesion receded from the first day after discontinuing the drug. In four days both were clear

COMMENT

The coincidence of time and place is remarkable. It considerably reduces the element of doubt, so often and inevitably present in the purely clinical diagnosis.

I would like to express my indebtedness to Dr. J. F. Gaskell for permission to publish this note; indeed, for the suggestion to write it.

Reviews

ALDOUS HUXLEY ON VISION

The Art of Seeing. By Aldous Huxley. (Pp. 143. 7s.) London. Chatto and Windus. 1943.

Aldous Huxley had bilateral keratitis at the age of 16 which left him with greatly reduced vision. As is common in such cases, his sight improved towards middle life. After he had become an ardent devotee of the Bates method of visual training his vision improved so that it was "twice as good as before." To repay a debt of gratitude to his benefactor and to make his art more widely known, Huxley has ventured into medical literature and written a book—*The Art of Seeing*.

Bates's hypothesis is, of course, well known to the medical profession: visual derangements and refractive errors are due to a deformation of the eyeball by a condition of nervous and muscular strain in the extra-ocular muscles; for this reason, according to Bates, the refraction may change "a dozen times or more in a second," if a child tells a lie, and so on. According to Huxley "disappointed love" can produce refractive errors; and myopia in children, while it may be influenced by physical factors, is essentially due to the fact that school children "are often bored and sometimes frightened . . . so that they emerge from the educational ordeal with myopia or some other defect of vision." The universal treatment in all cases is the induction of cerebral and ocular "dynamic relaxation," on the achievement of which the eye becomes normal. This desirable condition is attained by exercises which include palming (covering the closed eyes with the palms of the hands and imagining a beautiful scene), butterfly blinks, relaxed breathing, sunning ("letting go and thinking looseness," and turning the eyes to the sun), swinging (rhythmic swaying of the body while looking out of a window to make the mind "friendly to movement" and "soothe" it "as do the movements of the cradle"), nose-writing (writing with an imaginary pencil attached to the end of the nose), flashing with dominoes, shifting, rubbing and kneading the upper part of the nape of the neck, and a host of other procedures which Huxley admits are undignified but which he assures us permanently help the vision.

Whatever be the value of the exercises, it is quite unintelligent of Huxley to have confused their advocacy with so many misstatements regarding known scientific facts. It has been shown that the hypothesis upon which these methods of treatment are based is wrong; but Huxley, while admitting he is ignorant of the matter and unqualified to speak, contends that this is of no importance because the method works in practice and gives good results; it comes into the category of "art," not of "science." This argument is perfectly allowable, for in other spheres than medicine empirical methods have often produced effective results the rationale of which may be mysterious. The most stupid feature about his book, however, is that he insists throughout on the physiological mechanism whereby these exercises are supposed to work. It would at least have been logical if he had continued to allow the reader to assume that he was speaking in ignorance of anything except results. He only borders on the ridiculous when he says that these methods result indirectly in the relief or cure of many serious diseases of the eyes, such as glaucoma, cataract, iritis, or detachment of the retina, because they "reduce nervous muscular tension, increase the circulation and bring back the *vis medicatrix naturae* to its normal potency." Like the bonesetter who treats by forcible manipulation every joint whether rheumatic or tuberculous, or most obsessionists who believe that every virtue resides in one particular drug or practice, he treats all visual troubles as one all-embracing unity, all amenable to one sovereign remedy.

There is, of course, another side to the argument. There would appear to be no doubt that these exercises have done Aldous Huxley himself a great deal of good. Every ophthalmologist knows that they have made quite a number of people with a similar functional affliction happy. And every ophthalmologist equally knows that his consulting-room has long been haunted by people whom they have not helped at all. Huxley is quite right when he says that there is a tendency for the ordinary person, when there is a falling-off in vision, to "hurry off to the nearest spectacle shop" and there get fitted for a pair of glasses by someone who has "no knowledge of him as a physical organism or as a human individual." Nothing could be worse medicine than the indiscriminate and mechanical prescription of spectacles. He is quite right in saying that visual disabilities are often muscular and often psychopathic in origin. But every competent ophthalmologist treats the former with curative exercises (of a more scientific type than those recommended here), and, in the second case, at the least should advise the patient of the origin of his difficulties and suggest steps for their amelioration. For the simple neurote who has abundance of time to play with, Huxley's antics of palming, shifting, flashing, and the rest are probably as good treatment as any other system of Yogi or Coué-ism. To these the book may be of value. It is hardly possible that it will impress anyone endowed with common sense and a critical faculty. It may be dangerous in the hands of the impressionable who happen to suffer from glaucoma or detachment of the retina, and undoubtedly will be dangerous in the hands of the anxious parent of a myopic child who may be misled into neglecting the fundamental medical problems of growth, constitution, endocrinology, and rational ocular care, and may be persuaded to subject it to dangerous eye-strain in the absence of spectacles. But the greatest value of the book will be to the psychiatrist as an intimate and revealing self-study in psychology.

STEWART DUKE-ELDER.

ENCEPHALITIS

Encephalitis: A Clinical Study. Edited by Josephine B Neal, M.D., Sc D., F.A C.P. Foreword by Hubert S. Howe, M.D. (Pp. 563. 42s.) London: H. K. Lewis and Co 1942.

This book, edited by Josephine B. Neal, is a publication which has been rendered possible by the Matheson Commission for Encephalitis Research. It covers the whole field of encephalitis as that term is used to describe both those diseases known to be due to infection of the brain with neurotropic viruses and the demyelinating disorders, the aetiology of which is still obscure. Different authors, including Dr. Neal, discuss the clinical features, epidemiology, pathology, and treatment of encephalitis. Each section is followed by references, and the book is thus a comprehensive review of what is known of the subject, or, perhaps one should say, what was known when it reached the printers, for there are important new observations on the epidemiology of St. Louis encephalitis and equine encephalitis which are too recent to have been included. It would have been more valuable if much of the space devoted to encephalitis lethargica—about half the book—had been allotted to poliomyelitis. Encephalitis lethargica is not now of sufficient clinical importance to justify such a lengthy recapitulation of what has already been published in earlier volumes by the Matheson Commission, and in any case is in all the textbooks. Poliomyelitis is as much entitled to be included in a book on encephalitis as the Guillain-Barré syndrome, which finds a place in this one, and, as recent work has shown, it has close epidemiological affinities with several forms of encephalitis. It is somewhat confusing, too, in a book describing so many forms of epidemic encephalitis to limit this term to encephalitis lethargica. The book will be found useful, especially by neurologists, paediatricians, and public health experts.

CONTROL OF SCABIES

Scabies. By Kenneth Mellanby, Ph D. Oxford War Manuals. (Pp 81. 5s.) London: Oxford University Press. 1943

Practitioners will welcome the opportune publication of Dr. Kenneth Mellanby's Oxford War Manual on scabies. Some such authoritative production has been clearly required to establish a settled policy in treatment and to separate the good from the indifferent or the actually bad. Thus on page 60 there is printed a table showing the comparative efficiency of different methods. Sulphur ointment and benzyl benzoate emulsion come through the test well, achieving nearly 100% of cures. On the other hand, sulphur taken internally is shown to be completely valueless; and many other methods, despite popular advocacy, make very poor showing—sulphur soap, for example, achieving only 17%, and the thiosulphate–hydrochloric acid method a meagre 25%. Dr. Mellanby is of the opinion that disinfestation of contact garments and bedding has been over-emphasized, and that, as the Ministry of Health has decided, disinfestation of the clothing and blankets of scabies patients may reasonably be dispensed with (p. 42). In this connexion the opinion of Ferdinand Hebra is often quoted, though not by Dr. Mellanby. Hebra was certainly against formal disinfection by heat or vapour. Whether he was equally opposed to simple hygienic measures such as washing and ironing is uncertain, as his statement is a little confused. In any case Dr. Mellanby allows these methods, or others of a more searching character, where it is considered necessary to use them.

The way in which scabies is transmitted must obviously be closely bound up with disinfestation, although we have perhaps still to decide the usual means of dissemination. Scabies, Dr. Mellanby tells us, is essentially a domestic disease, and bedding is certainly able to transmit it under favourable conditions. He also lays stress on the sleeping partner. He mentions that, in the last war, men in the trenches may have transmitted scabies among themselves to a limited extent. This last observation seems improbable, because it was when troops were in rest, and clothing was removed and communal blankets were in use, that conditions favourable to contamination arose.

The author has completed a brilliant and successful research. Both the practitioner and the expert will find much that is original, and in the details of treatment and diagnosis a clear and simple description of the necessary facts and procedure. Dr. Mellanby has made a good job of it.

Notes on Books

Dr. WILLIAM J. DIECKMANN wrote his monumental treatise *The Toxemias of Pregnancy* for a dual purpose—to correlate recent advances in obstetrical physiology for the benefit of the obstetrician, and to present the non-obstetrical investigator with the facts of the physiology and pathology of obstetrics. By means of this form of "pincer movement" he marshals all the available material for a co-ordinated assault on that elusive enemy, the aetiology of pregnancy toxaemia. The material collected is imposing and skilfully arranged in six sections. These deal with the classification, incidence, and pathology of the toxaemias of pregnancy; normal and abnormal physiology; the aetiology of eclampsia; clinical aspects of the toxaemias; treatment; and maternal and foetal prognosis. As might be expected in a work so comprehensive, reference to other papers is frequent, and a valuable list of these references is summarized at the end of each chapter. This cannot have been an easy book to write, and in spite of its concise and lucid text and excellent illustrations it is not an easy one to read, but as a book of reference it will be most valuable to research worker, teacher, and clinician. It is published by Henry Kimpton at 37s. 6d.

Preparations and Appliances

A NEW ST. MARK'S HOSPITAL DILATOR

Mr. W. B. GABRIEL, F.R.C.S., writes:

The St. Mark's Hospital pattern of rectal dilator has proved, over a course of many years, to be an invaluable instrument in the treatment of patients suffering from conditions associated with spasm of the anal sphincter or contraction of the anus. In the after-treatment of surgical operations on chronic anal fissures, certain fistulae, etc., it is indispensable. Owing to the shortage of metal and labour the chromium-plated metal dilators have lately proved difficult to obtain, so at my suggestion Messrs. Allen and Hanburys have manufactured a dilator in glass, 3½ inches in length, and instead of a graduated taper the new model has a more "streamline" design which permits the maximum diameter of 1 inch to be reached about 3/4 inch proximal to the flange. This enables the full dilatation to be applied not only to the anal margin but to the entire length of the anal canal. The dilator is not composed of solid glass but is stout enough to stand boiling and "fair wear and tear"; it is light and easy for the patient to handle, and it is inexpensive. I think the glass dilator looks less formidable to the nervous patient than the metal one, and in practice I find that it passes very easily and is undoubtedly efficient.

PSYCHIATRY IN THE GENERAL HOSPITAL

Whatever may be the ultimate scope of the new physical methods in the treatment of mental diseases they have collateral advantages of no inconsiderable kind. Their tangibility makes them easily acceptable by the layman, sometimes perhaps dangerously acceptable; and for the same reason they have an appeal to medical men in general, who, somewhat to their own detriment, are still apt to regard mental diseases as things apart from their concern. The actual physical treatment of mental disease which is in use, for example, at the Sutton Emergency Hospital, and described by Dr. Dalton Sands in this number at p. 628, should have the effect on many people of bringing mental diseases within the same category of thought as physical ill-health. The effect, moreover, on the staff of a hospital which carries out these new therapeutic measures is to create an atmosphere of activity, interest, and hope which it was extremely difficult to create before in any hospital devoted to the care of the mentally disabled. About its moral effect on the patients themselves there is no doubt whatever. They above all people appreciate the reality of the methods and the amount of attention that they receive from doctors and nurses in the process—even apart from the actual results in curtailment of suffering. But there are still greater advantages. Early treatment becomes more possible because both patients and relatives are willing to accept it, and Sands's paper shows that a general hospital can become a suitable place for the treatment of many mental illnesses which hitherto have had to be sent to special hospitals.

To bring mental disease back into close contact with general medicine, from which it should never have been allowed to separate itself so long and so far, is the most fundamental step that can be taken in any programme of advance, not only in psychological medicine but in medicine as a whole, because it profits both realms. And any reorganization of medical services now being contemplated which ignores this will fail lamentably to provide the comprehensive service advocated by Sir William Beveridge. If "mental medicine" is properly integrated with "physical medicine" the patient, whether his illness shows itself as a mental or physical reaction, is much more likely to come to be regarded as a personality rather than as a collection of individual organs. No doctor who takes the narrower point of view can hope to be as effective in his own specialty as he could be if he remembered always that his patient has a social meaning as well as a liver or a heart or a thalamus. As an estimate of what can come to pass in this direction Sands's paper is worthy of note. In two wards in a general hospital with 46 patients suffering from nearly all varieties of mental illness, short of the severely disturbed type, 80% of them were returned to ordinary life cured or much improved with the aid of insulin, electric shock, continuous narcosis, or even leucotomy. The consequences of the success of a policy of this kind can be very great. It makes the introduction of psychiatric wards in a general hospital more desirable and more practicable than ever before. Such wards as already exist for this purpose in King's College Hospital and in the Middlesex Hospital can look forward to a wider usefulness, and the introduction of entire psychiatric units such as the York Clinic at Guy's Hospital is additionally justified. It would be a pity if enthusiasm for the provision of facilities for psychotherapy in general hospitals were to obscure the need for providing in the same hospitals facilities for modern psychiatric treatment by physical means. The dangers of compartmentalism in medicine should be stressed.

It is of course necessary to remember that this particular experiment at the Sutton Hospital was carried out with a prognostically favourable group. On the whole they were women who had broken down under special stress and for the most part fairly recently. They were all fairly young, and it has to be remembered also that similar cases can do well if put in really suitable surroundings and given adequate rest and proper general care. It is true also that there is some risk of exaggerating the effect of such methods. Statistics of shock treatment tell a very contradictory story at the present time: this is in regard to ultimate results rather than to duration of illness, which they undoubtedly shorten. At the same time it is noticeable that with various shock treatments something may happen to the doctor as well. His judgment of the clinical state of the patient after treatment seems to be rose-coloured by expectation, so that where formerly he would have prided himself on his skill in detecting residual symptoms following apparent recovery, he is now rather apt to imitate the Nelson touch, in the manner of the times perhaps, and to fail to see them altogether—a kind of professional amaurosis, psychologically determined. But there can be little doubt that even the most ideal surroundings and the most special care would fail to produce satisfactory results as speedily as these newer methods. And, whatever methods of treatment and prevention are eventually found to stand the test of time, the administrative temptation to split the whole person into two parts—"mental" and "physical"—must be withstood by those who care for the sick.

MASS RADIOGRAPHY UNITS

Mass miniature radiography has proved its usefulness in the Services—particularly the Navy—for the detection of chest abnormalities, but its extension to the civilian population, as encouraged by the Ministry of Health, brings in some special considerations and difficulties. It is one thing to require people in a disciplined Service to submit themselves for examination, and quite another to persuade members of the public of its necessity or value. At the invitation of the Minister a subcommittee of the Advisory Committee on Tuberculosis, including a number of well-known radiologists, was set up to consider the establishment and operation of a scheme, and the result is published in the form of an *Advisory Report on the Working of a Mass Radiography Unit*. Incidentally, let us plead for the adoption of the term "fluorography," which is the term used by de Abreu of Brazil, who devised the method. The method depends upon the photography of the image obtained on the fluorescent screen. It is true that the image is obtained by x rays, but the process so far as the 35-mm. film is concerned has little relation to diagnostic radiography as commonly understood, and on the analogy of fluoroscopy the term "fluorography" suggests itself. The subcommittee lays it down as essential that only standardized methods must be used. Improvisations are to be discouraged. The report sets out the standards for the radiographic and photographic apparatus, the screen for viewing the enlarged image, the record card which ensures that each radiograph is related to the individual concerned, and the terminology to be used in describing the findings either of pulmonary disease or of cardiovascular abnormalities. The apparatus consists of four principal parts: high-tension transformer, control panel, *x*-ray tube and stand, and screen and camera unit. The problem of portability—the apparatus weighs about a ton—with a generator to supply current offers some difficulties at present, so that use must be made of fixed sites of operation in fairly well populated areas. The housing of a unit requires *x*-ray room, dressing room, dark room, projection room, and rooms for medical director and staff. The procedure suggested is for groups of sixty or so to attend at half-hour intervals (in the Services, we believe, it has been possible to deal with up to 200 an hour). The individual will first obtain a record card from the clerk, and the number of the card will appear in the photograph; after returning from the *x*-ray room he will surrender his card to the clerk, who will enter the particulars in a day book.

The medical director of the unit, preferably a member of the tuberculosis staff of the authority, working under the medical officer of health, will be assisted by a radiographer and a technician, and the services of a consultant radiologist will be available. The medical director's work will consist of daily attendance to interpret the films; but, the work being tedious, the sessions should not exceed one and a half hours, and he should have clinical duties in addition. The task of examination should not be undertaken by two persons at once, because there might be a tendency for each to trust to the other and for the attention to wander. The object is simply to sift out the photographs which suggest an abnormality. When an abnormality is found the subject is recalled and a full-size skiagram taken, preferably at the clinic where the mass radiography is done, so as to avoid any premature association with the tuberculosis dispensary, with its psychological disadvantages. The result of the second examination is sent to the subject's private doctor, with, if there is ground for suspecting tuberculosis, a recommendation to consult the tuberculosis officer; and at this stage, of course, the clinical and radiological staff of the tuberculosis service co-operate. The examination will disclose conditions other than tuberculosis (in some figures for the Navy which we have seen 25% of the chest abnormalities were due to non-tuberculous lesions), but it is thought that in view of wartime shortage of doctors the tuberculosis officer should have the chief responsibility for dealing with these cases also.

There remains the great difficulty of the choice of subjects for examination. Here discreet propaganda will be necessary. Mass radiography cannot be forced upon the public. People must be told what it offers, and the importance of what it may discover must be made clear without exaggerations which would bring discredit on the procedure. It is suggested that the members and advisers of the local authority should be the first to seek examination, followed by young persons leaving secondary schools. The approach to people already in employment must be made with care. Any attempt to make examination a condition of employment must be discouraged—at least until the idea of routine examination of persons apparently healthy is more generally accepted. If it is proposed to examine employees in any factory the representatives of the trade unions concerned should be approached. Statistical information might be given to an employer, but only if it did not prejudice individual employees. Equally the co-operation of the works medical officer might be sought, but only if there was no suggestion that his participation would prejudice the confidential nature of the examination. The matter is difficult. No eager queue of examinees is to be expected in the initial stages. Central and local propaganda is necessary, but this must be in wise hands, otherwise it may deter more than it persuades, and in some cases an undesirable "tuberculophobia" may be created. It might be stressed that mass fluorography aims at discovering how many people have healthy lungs.

TROPICAL HYGIENE

Prof. Douglas Lee of the University of Queensland has published a very useful "Basis for the Study of Man's Reactions to Tropical Climates,"[1] with a bibliography of 350 references. In this he considers the mechanism of loss of heat from the body, and the bodily reactions to diminished heat loss, the adaptive reactions and failure of such adaptations, with consequent heat stroke, heat exhaustion, heat cramps, and superdehydration of the body. He says that very little is known of the mechanism of acclimatization. In discussing climate and loss of heat he deals in particular with the Queensland climate, with the habitability of such tropical regions by white men, and with means of protection against heat elements in climate. He finds that Queensland as a whole is suitable for settlement by the white race, but selection and individual adaptation are necessary for the more tropical parts: Cape York is not a suitable region. In dealing with protection against heat he recommends that for hot dry climates outdoor clothing should be stout, extensive, and loose to permit mild convection currents set up by body movement; such clothing, shielding the body from radiation and hot air, is worn by the Arab. In hot wet climates light, porous, scanty, and loose garments are required so as to allow free removal of air saturated with evaporated sweat. When the body is exposed to the sun in such climates it needs some light protective covering, leaving ample ventilation of the limbs and neck. Underclothing is not necessary in hot dry climates, but further outer protection is needed at nightfall when the temperature drops. The use of light underclothing in hot wet climates may be of advantage for soaking up sweat that would otherwise roll off the body. Radiant energy has no specific local effect upon the brain, but a broad-brimmed hat is needed in hot dry climates to protect against the warming of the whole body by radiation, and to prevent glare. In hot wet climates there is much less need for headgear.

As to housing, the thick-walled, small-windowed, heavily shuttered Arab house set in a courtyard and kept closed from early morning to late afternoon is suitable for hot dry climates, while the lath-built, thatched, airy dwelling of the Polynesian is suitable for hot wet climates. In fact the rules for housing correspond to those for clothing under the two conditions. In hot dry climates interference with air movement by fly-screens and mosquito-net is not detrimental to body cooling, whereas in hot wet climates it is disadvantageous. A lowering of air temperature in a house on hot dry days can be effected by a water-blind kept wet by slow dripping from a pipe or siphoning from a trough, with a breeze blowing through it from a fan or otherwise. This is the simplest method of air-conditioning to be used if water is available. The large medium-velocity overhead fan is preferable to the high-velocity table fan, but increased air movement may not help in hot dry climates when the air temperature is higher than that of the body, except of course for carrying away the heat of a cooking stove. Increasing air movement in hot moist climates affords great relief by favouring evaporation of sweat. Full air-conditioning plants are a public necessity in at least half of Queensland. There are great commercial possibilities in the provision of such plants in tropical climates, as well as at home, after the war. As to personal habits, excessive exercise and use of protein are to be avoided; under-activity is also a danger: one must not slip into lax habits of mind and body. A balanced diet, moderation in alcohol, great cleanliness, and avoidance of infection are all required in the Tropics. There should be a greater intake of fluid than is customary; and for heavy workers an additional 1/4 oz. of salt a day in hot, dry periods to make good the loss in sweating.

---

Prof. Lee's study will stimulate to combined inquiry research workers who have hitherto felt isolated in a maze of conflicting opinion.

HEALTH UNITS FOR THE WEST INDIES

A large-scale demonstration of the health unit system—by which it is hoped to improve the standard of health throughout the West Indies—is being staged in Jamaica to serve as a model and training ground for twelve other schemes in Jamaica, and many more throughout the islands. The health unit, a new idea for the Colonies, is an organization which provides a small community with the means to prevent and cure disease. Its main functions are seven: health education, ante-natal and maternal care, child welfare, school medical work, prevention of endemic diseases, control of endemic diseases, and sanitation. The work of the unit is carried on from a centre, where a medical officer of health has his office. Clinics are held for treatment, and an important feature is a meeting-room for talks, lectures, and demonstrations. Away from the centre will be branches, staffed by nurses and midwives, who will also visit the people's homes. Village health leagues will be formed, and the centre will put out health propaganda. The Jamaica Centre is to have a model venereal disease clinic, and start an intensified campaign against yaws. The underlying assumption is that with good team work the health unit system can accomplish far more than a much larger number of doctors working independently could do; it can get into close touch with the people and can be linked with social welfare, agriculture, education, and other efforts to raise the standards of rural life in the West Indies.

FOUR-YEAR PLAN FOR CHILDREN'S NURSERIES

Lack of suitable family houses and the improvised dwellings that will be used immediately after the war are among the reasons put forward by the National Society of Children's Nurseries for an increased demand for children's nurseries after hostilities end. The chairman of the society, in a memorandum which has been sent to the Minister of Health, states that about 16% of children attending school for the first time at the age of 5 suffer from defects, most of them preventable, due largely to bad housing, poverty, ignorance of mothercraft, overwork on the part of the mother, and the absence of regular and frequent supervision. A good deal of help, he points out, is given to mothers at infant welfare centres, but attendance at these centres falls off after the child reaches the age of 1 year, while there is ample evidence of improvement in the physical and mental development of children who attend regularly. Nursery provision should be an integral part of reconstruction, and no new housing scheme should be considered complete without it. The memorandum then describes a four-year plan for children's nurseries. It says that if a start were made within a year of the end of the war, premises to accommodate 300,000 children up to the age of 5 and trained staff could be available within four years. The children would fall into two groups. In the first would come those for whom full-time nurseries are necessary because their mothers go out to work, or because of sickness in the home, or for other reasons. One-third of the provision—100,000 places, which is equivalent to approximately 4% of the child population between 2 and 5 years of age and 2½% of those under 2—would be allocated to this group. Nurseries for these children would have to be open 5½ days a week for at least 9 hours a day and for 52 weeks a year. In the second group would be children under 5 who require a nursery day of 7 hours for, say, 48 weeks a year. These 200,000 places, it is suggested, would be used to the best advantage by giving a day's holiday each week to the mothers of 1,000,000 children. It is estimated that the cost in group 1 would be 3s. 6d. a day and in group 2 3s. a day, of which the parents would pay 1s. A foreword to the memorandum says that the plan, by its nature, constitutes a "charter for mothers." In addition to ante-natal and post-natal clinics, improved midwifery and lying-in services, and maternity benefits in cash, such a charter must include: (1) suitable housing with the benefit of modern labour-saving devices; (2) children's allowances; (3) training in mothercraft; and (4) proper provision for a regular weekly holiday. It is good to know that the needs of the working mother are not being overlooked.

PATHOGENY OF THE SPRUE SYNDROME

It is now generally agreed that tropical sprue, idiopathic steatorrhoea, and coeliac disease are varieties of the same disorder—the "sprue syndrome." The pathogenesis of this syndrome is still a matter for discussion, although it is generally agreed that it is a disease of malnutrition, the primary defect being faulty absorption from the intestine, particularly of fat and carbohydrate. Verzár[1] originally suggested that fat, like carbohydrate, is absorbed from the intestinal mucosa by a process of hydrolysis, phosphorylation, and resynthesis to neutral fat, the failure in sprue being one of phosphorylation due to lack of adrenal hormonal control. This notion has been disproved by a number of workers. Stannus[2] has now come forward with a novel hypothesis to explain the defect in intestinal absorption. He states that the absorption of neutral fat in sprue is normal, but that of fatty acid, glycerol, cholesterol, and glucose is defective. The loss of power to absorb these is due to failure of phosphorylation, an essential process for their absorption by the intestinal mucosa. Neutral fat and fructose are normally absorbed without phosphorylation, and this would explain the success of the older methods of treating sprue with strawberries and bananas. Calcium is lost to the body because it forms insoluble soaps with the free fatty acids, and phosphorus is lost by the defect in phospholipid formation resulting from failure of phosphorylation. The loss of calcium and fats, with their fat-soluble vitamins (A, D, K), is responsible for the bone changes, tetany, and failure of blood-clotting so often seen in the sprue syndrome. The mass of unabsorbed fatty acid and gas due to the fermentation of unabsorbed glucose causes intestinal delay and passive distension, together with other signs commonly demonstrated radiologically. Like Verzár, Stannus believes that the physiological lesion in sprue is failure of phosphorylation, but that this is due not to adrenal insufficiency but to a defect in the enzyme system catalysing phosphorylation. He believes[2] that the coenzymes of this system are members of the vitamin B_2

complex, including riboflavin, nicotinic acid, pyridoxine, choline, and possibly other members. The observation of Birch[3] that pyridoxine plays a part in the absorption of unsaturated fatty acids by the intestinal mucosa and their incorporation into phospholipids suggests that this member of the vitamin B complex may play a part in the pathogenesis of sprue. It also seems possible, as Stannus points out, that the loss of certain phospholipids containing unsaturated fatty acids may explain the causation of anaemia in sprue, and the nature of the fatty acids in the diet may even be a factor in determining the geographical distribution of the disease.

These observations would explain the beneficial effect of liver, rich in the vitamin B complex, in sprue. The response of the sprue patient to parenteral liver therapy is beyond all doubt. The hypothesis of Stannus receives support from the observations of May and his co-workers,[4] who have recently shown that the absorption of fat and glucose, the intestinal motility, and indeed the whole clinical course of coeliac disease are favourably influenced not only by crude extracts of liver given parenterally but also by mixtures containing vitamin B_1, riboflavin, nicotinic acid, pantothenic acid, and pyridoxine given parenterally. Oral therapy gave unsatisfactory results. It is known that both riboflavin and coenzyme I—a complex containing nicotinic acid amide, adenine, pentose, and phosphoric acid—may function in the transfer of phosphoric acid, and it is possible that other members of the vitamin B_2 complex may do so as well.

THE PERIPHERAL NERVES IN RHEUMATOID ARTHRITIS

The part played by the nervous system in the pathology of rheumatoid arthritis has often been investigated on account of the trophic features which the disease frequently presents, and for this reason the term "atrophic arthritis" is generally preferred in the U.S.A. A group of workers[5] at Wayne University, Detroit, have recently examined the condition of the central nervous system and the peripheral nerves in chronic arthritis. No specific or characteristic lesions were found in the brain and spinal cord. The sympathetic chain and peripheral nerves were next investigated in five cases, all of which presented the clinical and pathological features of chronic atrophic arthritis. The ages of the patients ranged from 49 to 73 and the duration of the disease from 4 to 16 years. In each instance nodules were found in the main nerve trunks of the limbs, situated in the perineurium and sharply circumscribed and inflammatory in character. In a large number of cases other than of arthritis no nodules of the same kind were found. The nodules strikingly resembled the subcutaneous nodules seen in rheumatoid arthritis. The endoneurium was not involved, and there were no pathological changes in the nerve fibres themselves. The authors recall that Koeppen[6] reported circumscribed perivascular lymphocytic infiltrations in the endoneurium of the sciatic nerves in three out of seven cases of rheumatic fever; in a second group of healed cases no such lesions were found. This observation is consistent with the fact that in rheumatic fever the subcutaneous nodules disappear with the decline of the active phase of the disease, whereas in rheumatoid arthritis they generally persist.

The conclusion drawn by the Detroit workers is that these nodules in the peripheral nerves are specific to chronic atrophic arthritis and should be classified under the term "rheumarthritic nodulous perineuritis." After a careful comparison between the symptoms of polyneuritis and those of atrophic arthritis it is suggested that the pains, paraesthesias, and trophic cutaneous symptoms may be due to the irritating action of these peripheral-nerve lesions. The lesions are considered to provide additional evidence of the close relation between rheumatic fever and chronic atrophic arthritis. The observations are too few to justify sweeping conclusions, but further research along similar lines is clearly called for. When the work was begun the nature of the results was not anticipated, and so it was not possible to correlate the severity of the nerve lesions with the degree of involvement of the joints. All the cases were of long duration and in middle-aged or elderly subjects. A similar investigation into the more acute types of shorter duration and in younger subjects would be of value: owing to the fortunately few opportunities of necropsy in such cases, could biopsy be brought in to help to clear up some of the obscurities in this common disorder?

BREADTH OR DEPTH IN MEDICAL TRAINING

Dr. W. M. Frazer, in his account of his recent visit to America, now printed as a report to the Corporation of Liverpool, comments in an informative manner, among many other subjects, upon the progress of medical education in the United States. The teaching of medicine as conducted there to-day has been a plant of rapid development. Twenty years ago American medical schools exhibited every grade of competence from the lowest to the highest. To-day, under the pressure of the medical profession itself, the dead wood has been cut away and the general level raised, though there still exists much more variety in the standards of different schools than in this country, where medical teaching has been regulated since 1858 under an *ad hoc* council. Dr. Frazer's impression is that the range of the medical curriculum in the U.S.A. is in some respects broader than ours. It is, for example, preceded by a course of cultural studies, and within the curriculum proper more emphasis is laid on such subjects as psychology, mental disease, preventive medicine, and paediatrics. On the other hand, there would appear to be, by comparison with this country, a shortage of clinical material in most American medical schools, occasioned in part by the relatively larger numbers of the students seeking a qualification, and in part by the fact that in voluntary teaching hospitals many of the beds are not available for instructional purposes, being private or semi-private. Either way there are not enough beds to go round, and American students have in consequence less ward work than ours. There are no clinical clerks or surgical dressers with duties and responsibilities in the handling of sick people. Teaching thus becomes didactic, aided by the distribution of typewritten or printed lecture notes, and the student's personal experience of the medical art on its practical side is inevitably more restricted than in Britain. While, therefore, a tendency to greater breadth in the outlook of their curriculum may be cordially conceded to the American schools, it may be claimed for the British system that it is better organized in depth, an arrangement of the first importance in the medical field as in the fields of war.

The Croonian Lectures for 1943 will be given before the Royal College of Physicians of London by Air Commodore C. P. Symonds on Tuesday, May 25, and Thursday, May 27, at 2.45 p.m. His subject is "Flying Stress."

The Hunterian Oration will be delivered before the Royal College of Surgeons of England by Mr. Victor Bonney on Wednesday next, May 26, at 3 p.m. His subject is "The Forces behind Specialism in Surgery."

THE REPRESENTATIVE COMMITTEE REPORTS

When the Representative Committee was authorized to enter into non-committal discussions with the Minister of Health an assurance was given that from time to time a report of the position would be made to the profession. This is the first such report.

In the past two months discussions have been proceeding. In the course of such discussions the Ministry put forward certain tentative proposals for a comprehensive medical service based on modified central and local administration and the employment of doctors as salaried officers, mainly whole-time, by a new type of local authority. The Representative Committee, considering that further discussion on the basis of such proposals would be unfruitful, met the Minister and the Joint Parliamentary Under-Secretary representing the Secretary of State for Scotland on Monday, May 17.

The Representative Committee made plain that, though not empowered to commit the medical profession, it believed that such proposals would be contrary to the public interest and unacceptable to the great majority of the profession, and sought their withdrawal.

The Minister, in reply, stated that the only Government commitment on the subject of a comprehensive health service was that outlined by Sir John Anderson in the debate on the Beveridge report in the House of Commons in February. The Government was not committed as yet to any particular form of medical service, and the Ministry proposals in question were put forward only as a basis of discussion. He agreed to regard these proposals as " in the discard " and to a re-examination of the whole position. He stated that after further full consultation with the Representative Committee and other bodies with whom discussions had been taking place he would proceed to express his conclusions in the form of a White Paper, which would then be open for consideration and discussion by the public and the medical profession before final decision by Parliament. He stated that he was not bound by any timetable in relation to the issue of a White Paper. He had not made up his mind, and he did not wish that the proposals already put forward should be regarded as in any way prejudicing the issue of a White Paper, the form and substance of which had not yet been decided.

These assurances were accepted by the Representative Committee, which decided to continue the non-committal discussions with the Ministry. The discussions will accordingly go forward on the basis of these assurances.

The Representative Committee asks for the continued confidence of the profession in pursuing these vital discussions on the understanding that at no stage will the profession be committed without prior consultation with it through the established machinery.

⁂ A report of the mass meeting of the Metropolitan Counties Branch of the B.M.A. held last Sunday to discuss the Government's proposals will be found in the *Supplement.*

On Wednesday, July 28, the Minister of Health will open in London the 26th annual conference of the National Association for the Prevention of Tuberculosis. The mass radiography scheme will be discussed during the morning, and the afternoon will be devoted to consideration of the new financial allowances for the tuberculous. Private persons interested in tuberculosis are welcomed to the conference, admission being by ticket only. The following instructions have also been issued from the Ministry of Health: " The Minister of Health has notified the N.A.P.T. that he has sanctioned in the case of county councils, county boroughs whose accounts are subject to audit, metropolitan borough councils, and joint tuberculosis committees the payment of the reasonable expenses which may be incurred in connexion with the attendance of two delegates, one of whom should be either the medical officer of health or the chief clinical tuberculosis officer. Individual applications to the Minister for sanction in respect of the conference will not, therefore, be necessary so long as the proposed expenditure is within these limits." The usual conference fee of one guinea has been waived owing to wartime conditions. Delegates are asked to send in their names and addresses as soon as possible to the Secretary-General, N.A.P.T., Tavistock House North, Tavistock Square, W.C.1.

BELGIAN FAMINE

Owing to the density of the population, which is mainly industrial, Belgium is probably experiencing war starvation to a greater extent than any other European country except Greece. A very sober account of what the Belgian people are suffering was presented at a famine relief conference in London recently by Dr. E. J. Bigwood, vice-president of the Belgian Red Cross Committee.

Before the war the average daily intake of the Belgian population was 2,850 calories per head, half of which was contributed by home-produced foodstuffs. During the four years of German occupation in the last war the figure was 2,250, and this reduction of 21% was held to be alarming. But during this war the ration cards (90% or more of the total food is rationed) allow only 1,250 calories, and, even so, the people do not get the amount indicated on the card Leaving out of account agricultural producers, who have a better diet of the order of 2,200 calories a day, but who represent only one-sixth of the population, and leaving out also the few rich people who can buy in the black market, Dr. Bigwood considered that the average figure might be taken as only 950 calories. Even more marked than the calorie deficiency is the reduction in protein intake. The bread ration is down to one-half of what it was in ordinary times, but the bread is hardly recognizable—a black, ropy, viscous substance comprising potatoes, barley, beetroot residues, and chestnuts. The fat content of milk has been reduced by more than one-half. Children under 3 receive three-quarters of a litre daily, and children between 3 and 14 are supposed to receive half a litre. Dr. Bigwood's figures referred to no later than the middle of 1942, but he said that the effects of partial starvation have already shown themselves both in vital statistics and in disease ratios. In normal times in Belgium there are annually 40,000 more births than deaths; in each of the years 1940 and 1941 the deaths exceeded the births by 21,000. School attendance has dropped by 40% in the urban areas through the sheer inability of the children to come. A very frequent complaint is hydroderma. The tuberculosis rate, which by 1930 had been reduced from higher levels to 1.18 per 1,000 of the population, had risen to 1.9 by the end of 1941. After Dr. Bigwood had spoken, M. Pierlot, the Belgian Prime Minister, added a few words of further entreaty to the British and American Governments to permit, within the limits imposed by the blockade, a certain amount of powdered milk and vitamin preparations, corresponding only to the medical requirements of those whose lives are actually threatened, to enter Belgium. He said that the Belgian Government has at its disposal sufficient funds for this necessary purpose, and has ceded to the International Red Cross a ship, now waiting at Philadelphia to undertake her first voyage of mercy. It will sail if, and as soon as, " navicerts " are obtained.

SOCIAL BACKGROUND OF HEALTH IN INDIA

During the Ling Physical Education Association's Easter Course at Homerton College, Cambridge, Dr. ALICE PENNELL (*née* Sorabji) spoke on " Health in India." She traced the effect of climatic conditions, diet, and customs, including religious taboos and traditions, on the health of the Indian people. Cases of goitre were most common in the salt ranges of the Punjab, malaria in damp Bengal, dysentery in the hills or plains where rainfall was excessive, eye diseases in places where desert sand and low rainfall were responsible for heat glare and dust, and elephantiasis in places where climatic conditions lowered resistance to disease, while many regions were conducive to the spread of epidemics such as cholera and plague. Various customs, notably the purdah system, involving lack of sunlight and seclusion to their own quarters, had affected the health of women, who in consequence suffered much from osteomalacia and difficult labour in childbirth. Superstition and ignorance, combined with the observance of many harmful traditions, had made the task of doctors in India exceptionally difficult. As a contrast to the disease in towns and among the sophisticated peoples, the healthy aboriginal tribes of Central India and the Pathans of the Afghan border were well worthy of consideration. Among the finely modelled women of these tribes childbirth was a natural function, after which a mother would immediately resume her work or rejoin in a march without any ill effects either on herself or on her new-born child.

Dr. Pennell spoke of the changes during the twentieth century, effected by willing and enlightened workers in the cause of science and health, who co-operated with British and Indian leaders in medicine in fighting the hydra-headed monster of ignorance, superstition, and disease. There were an increasing number of women doctors, women health visitors, and welfare workers; engineering reforms, canalization, and the building of big dams were correcting the grosser defects of desert land and bad irrigation, while education had helped much to combat retrogressive customs.

Reports of Societies

SURVEY OF VIRUS INFECTIONS

At the last meeting of the Fever Hospital Medical Service Group of the Society of Medical Officers of Health, with Dr. ANDREW TOPPING in the chair, Prof. S. P. BEDSON opened a discussion on recent work in the virus diseases.

Influenza and the Common Cold

The demonstration ten years ago by Smith, Andrewes, and Laidlaw that epidemic influenza was due to a virus, and the early and world-wide confirmation of this, had encouraged, Prof. Bedson said, the hope that specific prophylaxis might be made available for the control of this disease. That this hope has not yet been fulfilled was due to two main reasons: the virus of Smith, Andrewes, and Laidlaw (now known as influenza A virus) was not the sole cause of influenza, and influenza A has been found to comprise a number of serological types. A second virus causing influenza—influenza B virus—has been identified (Francis), but influenza A virus still remained the most important aetiological agent. An efficient polyvalent vaccine of this virus was difficult to prepare, but the observation of Horsfall and Lennette (1940) that cultivation of a strain of influenza A virus with a particular strain of distemper virus gave it a broad antigenicity covering all the serological types had made possible the preparation of a vaccine for field trial. This bivalent vaccine had given only mediocre results; the morbidity in the vaccinated had been about half of the unvaccinated. Immunization by spraying the nasopharynx with attenuated living virus or passive immunization by spraying with antiserum, both methods giving promising experimental results, awaited field trial.

No advance had been made since the demonstration by Dochez and his colleagues that some forms of this condition were due to a virus. A limiting factor in research on the common cold was the restricted host range of the causal agent; the chimpanzee and man alone appeared to be susceptible.

Primary Atypical Pneumonia

Outbreaks of this condition had been common, particularly since the beginning of the war. The condition appeared to be of virus aetiology, but more than one virus was concerned.

Psittacosis.—One virus known to cause atypical pneumonia in man was psittacosis virus. Diagnosis of human infection rested on the isolation of the virus from the sputum by mouse inoculation or the demonstration of specific antibody in the patient's serum by the complement-fixation test. The demonstration that psittacosis virus was antigenically complex, that one of the antigens was not destroyed by heating to 100° C., and that antibodies to the heat-stable antigen were regularly developed in human infections had made available a safe and stable antigen for use in the psittacosis complement-fixation test. It was now recognized that birds of the parrot family did not constitute the sole reservoir of infection. Naturally occurring infection had been demonstrated in the fulmar petrel (Haagen and Mauer, 1939) and in Iceland (Bedson, 1940). Infection in pigeon stocks has been shown to be widespread in America (Meyer and Eddie, 1942), and human cases from this source have been described in the Faroe Islands (Haagen and Mauer, 1939); and pigeons in this country have been found to be infected (Andrewes and Mills, 1943). Human cases derived from pigeons and the domestic fowl had been described (Meyer and Eddie, 1942). Strains of psittacosis virus from the different sources were antigenically similar, but differed in their virulence for the mouse and pigeon. It followed from this work that consideration of psittacosis as a diagnosis should never be excluded because the patient had not been exposed to psittacine birds. A recently published note (Baker, 1942) even suggested that cats and kittens might be the source of human cases, since in America they suffered from naturally occurring infections with a psittacosis-like virus.

Relation of Psittacosis with Other Viruses.—A large group of viruses existed of which psittacosis was the type. They were alike in morphology and staining reactions, and since they all stained by Castaneda's method, whereas other viruses did not, these viruses might be referred to as the "Castaneda-positive group." In addition to psittacosis virus the group included the viruses of lymphogranuloma venereum, meningo-pneumonitis (isolated by Francis and Magill, 1938, from a ferret inoculated with throat-washings from a case of "influenza"), a virus isolated by Eaton, Beck, and Pearson (1941) from cases of atypical pneumonia (possibly pigeon psittacosis), and the viruses of trachoma and inclusion conjunctivitis. Recent work by Rake and his colleagues (1942) had shown that all these viruses were closely related; experimentally in animals they cross-immunized to a considerable degree and they cross-reacted in the complement-fixation test. It was suggested that these viruses had a common ancestry and that what specific differences they possessed had been acquired as the result of long residence in a particular host species: psittacosis in a variety of birds (hence Meyer's suggestion to replace the term "psittacosis" with "ornithosis") and the viruses of lymphogranuloma venereum, trachoma, and inclusion conjunctivitis in man. It followed from this that the complement-fixation test used in the diagnosis of psittacosis infections, atypical pneumonia, and lymphogranuloma venereum had lost its specificity. A positive result merely meant infection with one of this group of viruses, and its significance could be determined only after consideration of the clinical and epidemiological evidence. Similarly the Frei test lost much of its specificity.

Primary Atypical Pneumonia due to Other Viruses.—Viruses of the psittacosis group appeared to be the cause of relatively few cases of atypical pneumonia. In this country serological sampling of outbreaks, both civilian and military, during the past two years had brought to light only three possible cases, and these were in American soldiers. These three gave weakly positive psittacosis complement-fixation tests, the significance of which was doubtful. In America, also, the majority of cases appeared to be due to some unidentified virus or viruses. Among the claimants as causal agents of atypical pneumonia one had to consider the virus of Horsfall and Weir (1940) isolated from atypical pneumonia and pathogenic for the mongoose; the virus of lymphocytic choriomeningitis, known to infect by the respiratory route and produce a pneumonitis; and the virus recently isolated from cases of atypical pneumonia in America by inoculation of the cotton rat (Eaton, Meikeljohn, Van Herrick, and Talbot, 1942).

Virus Meningitis

The virus of Armstrong and Lillie—lymphocytic choriomeningitis (L.C.M.)—appeared to be the cause of about one-third of the cases of aseptic meningitis. A second virus had been isolated from two cases of this clinical condition by MacCallum and Findlay, and named by them the "pseudo-lymphocytic choriomeningitis virus"; its importance as a cause of aseptic meningitis has yet to be assessed. The recent report of a case of infection with the virus of lymphogranuloma venereum (L.G.V.) in a negro in America (Sabin and Aring, 1942) in which the presenting symptom was meningitis, and from the cerebrospinal fluid of which L.G.V. virus was isolated, made it necessary to consider this virus in the causation of aseptic meningitis. In all cases of suspected aseptic meningitis the cerebrospinal fluid should be injected into mice intracerebrally and into guinea-pigs subcutaneously or intramuscularly in the thigh. Both species of animals were susceptible to L.C.M. and L.G.V. viruses, and the guinea-pig would confirm the diagnosis should it prove eventually that the case was one of tuberculous meningitis. In addition, serological tests for antibody to L.C.M. virus and possibly L.G.V. virus, should be made, a complement-fixation reaction being the test of choice.

Herpes

This condition was mentioned not because of its importance as a disease but because of the excellent example it provided of the symbiosis which could be established between a virus and its host. Herpes was common in a considerable percentage of individuals. There was no evidence that the infection in adults was exogenous. Levaditi and his colleagues had produced evidence that in those people subject to labial herpes the virus could be demonstrated in the saliva in between the attacks, and Andrewes and Carmichael (1930) and Brain (1932) had shown a very close correlation between the possession of herpetic antibody and susceptibility to herpetic eruptions.

Recently Dodd, Budding, and Johnston (1938) had shown that vesicular stomatitis in the first two years of life was herpetic, and that it represented a primary infection. This had been confirmed by Burnet and Williams (1939). It would appear that infection with this virus occurred in the early years of life, and that recovery resulted in the individual's becoming a carrier. With increasing age a physiological insusceptibility to infection developed, so that those who had escaped infection in the first two years of life would not later contract the infection and become herpetic subjects. In those who carried herpes virus the balance between host and parasite might be upset by a variety of factors—infection, fever therapy, excessive exposure to sunlight, fatigue, menstruation—allowing the virus temporarily to gain the upper hand and give rise to an attack of herpes. The importance of this work was that it disposed of the conception of the spontaneous generation of herpes virus, a view which found favour with some workers, such as Doerr.

Poliomyelitis

Owing to lack of time, mention of recent work on poliomyelitis had to be omitted. It had been intended to draw attention to the recent demonstration by Paul and his colleagues in America (1940) that the virus of poliomyelitis was present in the stools and could be demonstrated in the sewage of localities in which poliomyelitis was occurring. This made it necessary to recast our views on the mode of spread of this disease. The spread of poliomyelitis by droplets with the nasopharynx as the portal of entry was probably of minor importance, if it occurred at all. Infection most probably entered by the alimentary tract, the virus passing to the central nervous system by axonal routes at different levels.

Dr. Andrewes on Influenza

Dr. C. H. Andrewes said that he agreed with Prof. Bedson's remarks about influenza vaccination. If one used the best possible influenza A vaccine and injected it shortly before an influenza A epidemic, one might hope for a 50% drop in incidence of influenza A (but not necessarily of all "clinical influenza"). In less favourable circumstances no obvious benefit would follow from vaccination, which therefore could not be said to be as yet a practical proposition for widespread use.

The periodicity of influenza outbreaks in England had lately been such that we had had some every other year and a bigger peak every fourth year (as in 1929, 1933, 1937). Influenza A virus had been recoverable as a rule only in the odd years and especially in the peak years (1933, 1937). The expected epidemic in 1941 did not turn up, nor did influenza A appear in 1942 or (as yet) in 1943. The widespread but mild influenza now current seemed, on serological grounds, to be mainly influenza B. The virus was much more difficult to establish in experimental animals from B than from A cases.

ACTION OF DRUGS ON THE UTERUS

At a meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland on March 26 Dr. Edward Solomons and Dr. J. D. H. Widdess presented a paper on the action on uterine muscle of certain antispasmodics—trasentin, syntropan, and pethidine hydrochloride. The drugs were used clinically, and experimental work was carried out on the human uterus *in vivo* by the intra-uterine balloon technique as described by Chassar Moir. Further observations were also made on human uterine muscle (removed at operation) and animal uteri *in vitro*. The experimental results were as follows: Trasentin caused relaxation and diminution of contractions in the uteri of the rabbit and guinea-pig and of the human subject *in vitro*. This effect could not be observed in the human uterus *in vivo*. So far as the limited supplies available were used, syntropan showed a similar effect. Pethidine hydrochloride invariably stimulated the uterine muscle of the guinea-pig and rabbit *in vitro*, causing an increase in the force and frequency of contraction. On the human uterus *in vivo* the action of this drug caused, in the majority of experiments, slight increase in tone and frequency of contraction. Clinically, in a small series of cases neither trasentin nor syntropan proved satisfactory in the treatment of dysmenorrhoea. Trasentin produced drying of the mouth and unpleasant eye symptoms. On the other hand, pethidine hydrochloride gave relief in a high proportion of the cases in which it was used, a result probably to be explained by its central action as an analgesic. All the cases of dysmenorrhoea selected for this investigation were normal on gynaecological examination. During the investigations carried out by the balloon technique no relation could be observed between the incidence of powerful contractions of the uterus occurring naturally or by stimulation with pituitrin, and sensations of pain experienced by the patient. Neither could it be shown that contractions observed in patients suffering from dysmenorrhoea were any greater during menstruation than those observed in normal subjects.

Correspondence

Organization of Postgraduate Study

SIR,—It is fashionable at present to make plans for the future of the medical profession. One of the objects to be attained by such planning is stated to be the provision of adequate leisure for postgraduate study. This is a praiseworthy intention, but stops short just as it becomes most promising. A logical sequel would be "planning for postgraduates"; but this has not so far been mentioned.

In 1939 the main bodies responsible for the teaching of postgraduate medicine were the British Postgraduate Medical School at Hammersmith, the Fellowship of Medicine, and the North-East London Postgraduate College. These establishments were quite separate and did not co-operate with each other to any noticeable extent. In consequence, a student would often waste a great deal of time looking for the instruction which he wanted, visiting several hospitals and clinics in his search. Another difficulty was the absence of provision for general practitioner students. A few concentrated "refresher" courses were held from time to time, but these only partly filled the hiatus. The correspondence colleges provided tuition of a sort, but again did not go far enough. It is obvious that we must do better in future.

At least three distinct types of clinic are necessary in postgraduate instruction. First, the general revision course designed to meet the special needs of the general practitioner. This must not be a rushed cramming of recent advances in medicine and surgery, so often the case in the past. It should be organized by someone with knowledge of general practice if the greatest benefit is to ensue. Too often a specialists' symposium is rather overwhelming, but not permanently beneficial to the students. Next come the various special clinics at which instruction and practical experience may be obtained. Demonstrations of the injection treatment of haemorrhoids, performance of artificial pneumothorax, and so on, with opportunities for practice under supervision would be of the greatest help to many postgraduates who cannot attend regular courses. In this connexion should be mentioned the lack of provision for tuition in physical medicine. Let us hope that the newly formed British Association of Physical Medicine will do something to remedy this. Finally, we have the courses and classes for those desiring to take examinations for diplomas, higher qualifications, etc. In this case, also, there is room for co-ordination and improvement. Teaching advanced medicine and surgery is not something to be ashamed of, as certain institutions seem to think.

However, the greatest lack is the absence of co-ordination of the facilities available. Cannot the various bodies concerned get together and work for the benefit of the students, instead of continuing in splendid isolation? Here, if anywhere, is a case where medical planning is vitally necessary and urgent.
—I am, etc.,

Royal Hospital, Chelsea, S.W.3. TREVOR H. HOWELL.

The Case for a Shortened Puerperium

SIR,—I am sure that others besides myself have been interested in the recent outcry in the lay press about the shortage of maternity homes and facilities for mothers-to-be. One cannot condone such outbursts, even though they have a very definite foundation, but I think that we, as a profession, have been to some extent responsible for the present unsatisfactory state of affairs, largely because of our failure to make the best use of what accommodation is available. Indeed, I have a suspicion that something like a minor "racket" has arisen over maternity homes (particularly of the private nursing home type). I will say, however, the doctors are innocent but misguided participators in it, and if we are all honest with ourselves most of us will have to admit being guilty some time or another.

It has become the fashion in recent years to teach that having a baby is a simple job, unattended by any great danger provided that adequate care is taken of the mother before, during, and after childbirth. Such propaganda is admirable, and the standard of ante-natal care and midwifery nowadays is moderately good and is slowly improving. It is with after-care I wish to deal, and by that I do not mean the post-natal clinics but the immediate puerperium.

Despite the improved teaching, women (as well as many doctors) still fondly cherish the belief that childbirth is an exhausting experience that will leave them weak and helpless for months. To offset this it is becoming common to prescribe "a good rest" to follow the labour, and among the better-class patients this usually lasts a fortnight before any attempt is made to get the woman out of bed, let alone on her feet or out of doors. Indeed, the average woman paying for a stay in a nursing home now books for a stay of at least three weeks after her confinement. After her fortnight in bed she has become so weak from lying still and her muscles have lost so much tone that she finds it harder than ever to get up and about. Returning home in this state she calls in her doctor and is prescribed further rest by that well-meaning man. The vicious circle is started, normal muscle tone is not regained, and it may be months before the patient is anything like fit. And then her troubles begin. Backache—that gynaecological *bête noire*—due to strain on her spine inadequately supported by flabby and wasted back muscles, and prolapse, due to lack of support of the organs by weak perineal and abdominal muscles, all follow in due course. All this time the woman is a liability to her family: she has to have help in the home (a liability to the whole country these days); and instead of making her muscles do their job she runs off to get a nice firm corset to help "support her" (using up more of the country's labour, rubber, and other materials), which she thus condemns herself to for the rest of her life.

Is there any solution? Surely a more rational approach is to realize that the longer a woman remains on her back the weaker and more flabby all her muscles will become. (This is true of any condition which leads to confinement to bed.) I am certain from my own experience that prolapse is far more likely to arise in this way than from not allowing time for hypothetically torn ligaments to heal. Ligaments always depend on muscle tone, and there is no need to postulate any differences in the pelvic organs. It is also a known fact that many slighter degrees of prolapse are greatly benefited merely by exercises for the abdominal, pelvic floor, and back muscles. The obvious thing to do, therefore, is to make every effort to improve the woman's muscular tone, by exercises from the first day, by getting up early, etc., and the very worst thing that could happen is to leave her lying in bed for a fortnight. The concomitant improvement of the circulation which occurs will help to prevent venous stasis and white-leg, and will encourage the blood supply to the breasts in the first critical days of feeding. It is probably not wise to get the patient up before the fifth day, as the breasts tend to be heavy and uncomfortable, but by gradually increasing the exercise the patient should by the tenth day be walking and feeling strong. I believe that only for severe perineal tears should this be modified, and even for them continuous exercises in bed from the first should be given. (I make no mention of massage because active exercises are better than any amount of massage, and our masseurs have too much to do in other fields.) Mothers treated on these lines are happier, they feel themselves rapidly getting stronger from the start, they are able to go home and not be invalids when they get there, their psychological outlook is better, and they remain keen on natural feeding, which is so often blamed for causing "weakness."

May I plead for a little more thought and action on these lines? If we reduce the stay of our mothers from three to two weeks in the nursing homes and at the same time send them home well and fully able to undertake their household duties, then not only does more accommodation become available for other mothers but we are making better use of the reduced number of midwives and saving woman-power which might otherwise be needed to help in the home. I am aware that in the ordinary hospital women are sent home much sooner, and what a contrast there is between this class of mother (who in the majority of cases leaves the hospital fit and well) and the pampered well-to-do patient who thinks that her experience of labour (which is probably a harder job of work than she has ever done in her life before) is sufficient to justify her being an invalid and being waited upon hand and foot for several weeks afterwards.

I must add one word of warning. I have noticed (and it has been the experience of my colleagues) that nursing homes are encouraging longer stays. One supposes that a labour every three weeks is much less work and expense than one every fortnight, and the income from the patients remains assured. Added to this, the dangerous teaching of ill-informed nurses and midwives about the dangers of prolapse, etc., is doing much to foster wrong beliefs in the minds of the mothers, who appear to be regaled throughout their stay in the home by gruesome stories told by so-called professional women who should know better. Women have a pathetic faith in what other women tell them, especially about troubles peculiar to their sex, and a great deal of harm is being done by this vicious propaganda.—I am, etc.,

DENYS J. NEAL SMITH,
Richmond, Surrey Late Obstetric Officer, Charing Cross Hospital.

Advice on Sterility

SIR,—In view of the fact that at least 10% of married couples suffer from involuntary sterility it is obvious that the problem of such sterility is one of great national importance, not only because of the personal unhappiness it may cause but because of the urgent need to increase our present birth rate if a falling population is to be averted. Not all cases of sterility are as intractable as might be supposed from the literature on the subject, and many yield to quite simple advice. Only in so far as this fails is it necessary to institute more complex inquiry. In cases which continue to prove refractory, elaborate examination of both parties may be necessary.

Although many experts are interesting themselves in this subject, few facilities exist for a broad study of the problem and for that co-operation between gynaecologist and male genito-urinary specialist which is essential to its solution. Nor, indeed, is there much likelihood that the average country patient who seeks advice in this matter can obtain expert help.

The Family Planning Association has long been in touch with working-class family life through the medium of its contraceptive clinics, scattered throughout the British Isles. It believes that there is a great opportunity to reach a certain type of patient who is not likely to present herself at a hospital out-patient department complaining of sterility, but who is nevertheless deeply disappointed by finding herself barren. Many such women have already asked for help at F.P.A. clinics, thereby demonstrating the reality of the demand.

The association has formed an *ad hoc* committee which intends to organize clinics to deal with cases of sterility either by referring them, where necessary, to the appropriate hospital centres, or, where these do not exist, by providing such expert attention as facilities permit. Such sessions would be called "Motherhood Clinics," and would be held occasionally in the same premises as already existing birth control clinics. Details of such developments will be communicated later to the medical press. In this way there will be the beginnings of a nation-wide effort to eliminate the present distressing wastage of potential maternity.—I am, etc.,

HORDER,
69, Eccleston Square, S W 1. President, The Family Planning Association.

Resuscitation of the Drowned

SIR,—Dr. F. C. Eve's paper (May 1, p. 535) on complacency in resuscitation of the drowned is very timely in pointing out that Schäfer's method of artificial respiration has not been universally accepted as the most satisfactory manual method. Its main weakness is probably that it depends upon elastic recoil of the thorax to produce efficient inspiration. This difficulty is overcome in the Drinker combined method of artificial respiration (Drinker, C. K., and Shaw, L. A., *J. industr. Hyg.*, 1935, **17,** 243), which combines the prone pressure method of Schäfer with the arm lift of the Holger Nielsen method. In the Drinker combined method one operator applies pressure on the loins of the prone patient as described by Schäfer. A second operator kneels at the patient's head and grasps his upper arms. When the first operator relaxes his pressure (i.e., during inspiration) the second operator raises the patient's arms from the ground to facilitate inspiration. During the expiratory phase, when pressure is being applied to the loins, the arms are allowed to lie on the floor.

In the course of a comparison of different manual methods of artificial respiration in this department we were impressed by the superiority of the Drinker combined over the Schäfer method by the only criterion which can be applied experimentally—that is, the volume of the pulmonary ventilation. As the results obtained by trained operators on a small number of trained subjects may be misleading, we decided to compare these two methods when performed by operators comparable in skill to ordinary first-aid parties. For this purpose preclinical students in this department have during the last three years compared the efficacy of the Schäfer and Drinker combined methods as a class exercise. Each method was performed at the rate of twelve respirations per minute for three minutes on a normal subject, who had voluntarily suspended his breathing. During the second and third minutes the subject's expired air was collected in a Douglas bag and subsequently measured on a spirometer. (Collection over longer periods results in changes in the respiratory apparatus, probably in the tone of the muscles, which vitiates any comparison of methods.) The subject rested for ten minutes between the collections. In half the experiments the Schäfer method was first applied, in the other half the Drinker combined method.

The results show the ventilation of the lungs is 25% greater in the Drinker combined than in the Schäfer method. This difference is statistically significant. The detailed results are as follows:

Number of sets of results = 113.

Average expired air by Schäfer method = 8.70 litres per minute.

Average expired air by Drinker combined method = 10.88 litres per minute.

Mean difference, Drinker combined − Schäfer = $+25 \pm 2.0\%$.

Although the efficacy of instrumental methods such as Dr. Eve's rocking apparatus is not in doubt, it will always be necessary to train first-aid workers in a manual method which can be applied in cases where no instrumental aid is available, or during the interval when the patient is being transported to the instrument. In view of the above results we suggest that this simple addition to the Schäfer method might with advantage be incorporated in the training of first-aid workers. It can be applied to a patient immediately if two operators are available, or can be added later to the Schäfer method without cessation of respiration or alteration of rhythm if there is no second operator at first. The additional ventilation of the lungs thus produced may be just sufficient to tip the balance in favour of the patient.—We are, etc.,

Department of Physiology,
Manchester University.

W. V. WADSWORTH.

Ariboflavinosis

SIR,—The note of warning uttered by the writer of the annotation upon riboflavin and corneal vascularization (May 1, p. 545) is most timely. At the same time it is perhaps a pity he did not state the case more clearly, and say quite frankly that the whole fabric of ariboflavinosis may require much remodelling when the results of the more carefully planned investigations now being carried out in this country, the United States, and elsewhere become available.

Many of the difficulties have arisen as the result of lack of precision in clinical description and failure to define the terms used on the one hand and on the other ignorance of, or disregard for, the normal anatomy and physiology of the affected tissue, especially true, perhaps, of the eye, and then more particularly of the limbus. Your annotator exemplifies this very well when, in referring to *corneal vascularization,* he cites an article by Scarborough upon *circumcorneal injection,* as if the two were synonymous. Scarborough's observations, unchecked by slit-lamp microscopy, do not lead one very far. That so-called circumcorneal injection is commonly to be observed in the general population of this country and unrelated to riboflavin deficiency is well known; it was so recognized by Prof. Sydenstricker when in this country. At the same time he pointed out how necessary it was to exercise great care in attempting to interpret some of the tongue lesions which have been included in the ariboflavinosis syndrome.

May I urge, therefore, after a study of many of these conditions going back some thirty years, that we still exercise patience before arriving at any very definite conclusions concerning the signs of riboflavin deficiency. At the same time may I protest against the introduction into medical literature, as was done last year,* of the term "pseudo-ariboflavinosis."—I am, etc.,

London, W.1. HUGH S. STANNUS.

Incidence of Venereal Disease

SIR,—The amount of venereal disease in the last war, now called the First German War, was serious enough, as anyone who will read the British *Official History of the War,* volume 2, will realize. There were 400,000 cases in British and Dominion troops and 340,000 in American troops, a total of 740,000 reported cases.

Those concerned may be aware of the facts and some may have read my *Vision of the Possible,* which contains Lieut.-Col. Elgood's monumental memorandum on the conditions in the Port Said area in Egypt. Few people, however, have realized the manner in which the Americans acted after the war. They took one-day censuses in many of their cities, asking every medical practitioner to state confidentially how many cases he had under treatment on a particular day, and his estimate for twelve months. The profession responded well. The results varied, but led some men to come to the conclusion that there was no remarkable increase in wartime. In war, cases are reported and noted; in civil life we do not know what is occurring.

I have not read of any similar activity in Great Britain; and in Melbourne, though I offered to bear the cost. I met with a stone wall for reasons not worth discussing. The stone wall was friendly enough but remained solid. The cases reported are those in institutions, not the numerous cases in private practice. Until the American method is adopted we shall not know the facts. As regards the wartime cases, it must be remembered that only the reported cases count. The unreported cases remain a matter of conjecture.—I am, etc.,

Melbourne. JAMES W. BARRETT.

V.D. in the Merchant Navy

SIR,—In my experience during the war there has been considerable increase in venereal diseases among merchant seamen. The reasons for this are the long periods away from home, the increase in the amount of money that the men have to spend, also bad propaganda in the way of articles published in certain popular magazines, such as "The Five-day Treatment of Syphilis," "The One-day Treatment of Syphilis," and "The Five-day Treatment of Gonorrhoea." These indicate that the disease is easily curable, and, in the earlier part of the war, the great majority of cases of gonorrhoea responded well and rapidly to sulphonamide therapy, but gradually the number of resistant cases has increased. This increase was most remarkable in South Africa, where it would appear that two types occur—one with an incubation period of 4 days, which is the same disease as we get in this country; the other with an incubation period of 9 to 14 days. In the second type the onset is insidious and produces a pale milky discharge, and is almost always exceedingly difficult to cure. In one S. African port seventeen of the crew contracted gonorrhoea and only two of them responded to large doses of sulphapyridine and sulphathiazole. This is of importance, because seamen are liable to spread this resistant type of the disease in this country.

---

* "Pseudo-ariboflavinosis," M. Ellenberg and H. Pollack, *J. Amer. med. Ass.* 1942, 119, 790.

The treatment of men in the Merchant Navy always presents difficulty. A number of ships do not carry surgeons, and therefore adequate treatment is impossible, so that it is necessary for these men to be put ashore, where, even in the larger ports, there are no adequate facilities for hospitalization. In a large S. African city there are only 14 beds available for the treatment of venereal disease in Europeans. This means that the shipping companies responsible for the welfare of the individual have to keep him in a hotel or other lodging-house until such time as he can be repatriated. This unfortunate system allows a large number of men who are virulent carriers, with plenty of money and nothing to do after they have received their daily washout or weekly injection, to roam the town and spread the disease among the brothels and numerous enthusiastic amateurs who seem to abound in all ports in these times.

The treatment of syphilis is even worse than gonorrhoea; the Board of Trade regulations do not demand that antisyphilitic equipment be carried. In peacetime, when a man was able to choose the ship in which he worked, the international arrangement of receiving treatment in various ports was satisfactory; but now it is quite impossible for a man to say when he will be able to remain in port long enough to receive treatment. Periods at sea are frequently a month and over. Three times in the course of the last few months merchant seamen have come to me after I have lectured on this subject and they assured me they were told that they had been cured of syphilis by having twelve weekly injections of N.A.B. Each man produced a book showing he had a positive dark-ground, following which he had twelve weekly injections. One went so far as to say he had been told that he was fit to get married. I think further observation on this apathy, ignorance, or malpraxis is unnecessary.

If the ship surgeon carries venereal patients he should receive adequate information in time to make the necessary preparations. I quote two personal experiences.

> Two men were sent out from England to join the ship and they produced papers to show that they were suffering from syphilis. They stated that they had received injections but did not know the drug that was used. One did not know how many injections he had had.
>
> The other example I offer is that on the morning of embarkation for a long voyage 150 distressed British seamen came on board. I was assured by the Indian shipping master that they had been medically examined, required no treatment, and were fit to travel. However, I have been at sea for some time and am rather sceptical on such occasions, so I called a muster and found thirteen active venereal disorders among them. These men had all been attending the local hospital; they were suffering from primary chancre, chancroid, and gonorrhoea. In no case did any man have any papers stating the diagnosis or the treatment he had been receiving. Owing to the time factor it was quite impossible to obtain the necessary quantity of drugs to deal with the situation, so these men were sent ashore, which means going back to the hotels, to continue to be an expense to their respective companies and a prolific source of infection to the women of the town.

—I am, etc.,

Bournemouth. J. C. H. BROWNE.

Incidence of Pulmonary Tuberculosis

SIR,—It has been claimed that by means of mass radiography the incidence of tuberculosis could be ascertained, the cases discovered before they were a menace to their fellows, and so treated in the early stages that the disease could be eradicated. If we assume that it would reveal every case we have to realize that, as with any widespread infectious disease (at least 3% of all elements of the population are said to have active tuberculosis), all the cases and their contacts—i.e., the entire population—will have to be examined, preferably within the incubation period of the disease, and, in the case of tuberculosis, certainly within three months of exposure to infection. For the whole population this would necessitate the use of 1,000 units with their full staffs, and if, as now suggested by Dr. J. V. Sparks (March 27, p. 398), medical officers should report on 500 films per week we should need about 6,000 medical officers to interpret the films. Your correspondent Dr. N. P. Henderson (April 17, p. 487) states that even if each of the thirty units carries out 5,000 examinations per week "then some 10,000 bus loads per week will be proceeding throughout the country to cope with this new form of examination"; apparently with 1,000 units we should require 330,000 buses for the purpose. It has further been suggested that the thirty units are but a beginning, and that gradually these can be increased to include all the population—i.e., give us the equipment, staff, etc., cited above, for they are necessary if the goal cited by the Minister of Health is to be reached.

Has the immensity of the investigation in medical officers, technical staff, accommodation, and materials been considered by the Treasury? To carry out the investigation on relatively small numbers of the population, as can only be done with the thirty units—except, perhaps, in the gaols, where the outside contacts are few and not intimate—could not be regarded as a useful measure in preventive medicine. Even in the Services, with their close segregation, which permits of multifarious outside contacts not subject to inspection, the investigation must be conducted at least every three months to detect cases infected from outside, otherwise they would become foci of infection, the more dangerous because of the false sense of security given by the radiography. To impose it compulsorily, as suggested by some enthusiasts, on groups of workers, ignoring all contacts, would not be a contribution to preventive medicine, but would be an unjust penalization of the selected workers who happened to be so unfortunate as to be examined. How unfortunate is indicated by the aims of some officials. For instance, Flight Lieut. A. G. Evans (May 8, p. 565) states of the infected patient: "This type of patient should never be re-employed in an indoor industry, however well he may feel in himself, except in a light sedentary job where he has an office to himself. The fact that a patient has become temporarily sputum-negative is no guarantee that he will not again become sputum-positive under conditions of stress. One envisages that in the future there may be some form of industrial segregation of this type of case in the big industrial areas so that they can be usefully employed in indoor industry. It is only by such bold measures that we can hope to tackle efficiently the problems before us." And further: "It is hoped, and anticipated, that a considerable proportion of these cases, having been discovered in an early stage, will be suitable for artificial pneumothorax, which after preliminary induction in a sanatorium can be continued at the local tuberculosis dispensary." It sounds like compulsory leper colonies with official freedom to act.

How has this mass examination helped in the Services? Flight Lieut. Evans gives the results of 75,000 cases. He records the finding of 387 cases of inactive tuberculosis, 95 active without symptoms, 135 active with symptoms. He states: "It is wishful thinking to expect a majority of early cases at once, before the more advanced cases have been discovered in the preliminary surveys." Obviously, as in the scheme the detection of early cases depends entirely on the radiographs, he cannot include in his figures the early cases, with and without positive sputum, which do not show any typical radiographic lesion. Those who deny the existence of these cases confess an ignorance of the grossness of the lesion necessary in some cases to give radiographic evidence of departure from the normal. A comparative study of lesions and their radiographs, whether they are in soft tissues or bone, reveals that these lesions and their surrounding reactions are considerably in excess of the size suggested by the radiograph; and that in the lungs, which contain tissue of different densities, macroscopic lesions can be present without any radiographic indications.

Flight Lieut. Evans does not indicate in his classification which patients did or did not show clinical signs or give a history of family or other contact infection. The mass radiographic examination ignores these factors. Of the sputum-negative cases without symptoms but with evidence of active infiltration he states: "It is suggested that in the younger age groups so discovered the individual should be re-radiographed six-monthly for two years, then annually for three years. If the patient is then written off the dispensary books he will be given due warning, should any symptoms arise, to report first to his local practitioner." If a patient who has had active infiltration can be "written off," and not re-radiographed even annually without he reports the development of symptoms, why incur all this expense of periodically radiographing masses of the population who are happy and well? Why not leave it until they develop symptoms and report to their doctor, who should be alive to the significance of the symptoms, of the family history, infective contact, and, possessing a knowledge of clinical signs, can then refer the patient for further investigation by the tuberculosis officer? This method already provides more cases than we have either the accommodation or the staff to treat, and we still cannot control the infective person or prohibit the sale of unsterilized tuberculous milk.—I am, etc.,

Birmingham. JAMES F. BRAILSFORD.

Planning for Treatment of Head Injuries

SIR,—It is difficult to see what harm could be done to the patient in taking what Dr. T. Rowland Hill (April 10, p. 457) and Dr. Harold Parsons (May 1, p. 550) consider an over-optimistic attitude in the management of head injuries. On the other hand, it is obviously harmful to adopt the pessimistic bias expressed in Dr. Hill's routine question: "Do you feel the same man that you were before the accident or have you never fully recovered from it?" With our present knowledge it is impossible to disentangle the "organic" and the "psychogenic" factors of the traumatic syndrome. Early reassurance and graduated exercise are a definite help and have not proved to be dangerous. The relatively early social readjustment following their application can safely be regarded as an asset both for the individual and the community. Whatever the cause and intensity of the headaches, etc., may be they will be borne more easily by a person who considers himself fit for his job. On the other hand, cases treated by prolonged rest in bed and without some kind of psychological help early on do indeed have a bad prognosis.—I am, etc.,

Radcliffe Infirmary, Oxford. FRANCIS SCHILLER.

Control of Head Lice

SIR,—In Memorandum No. 230A/Med. published by the Ministry of Health, entitled, "Memorandum on Control of Head Lice," the claim is made that lauryl thiocyanate "is undoubtedly lethal to lice and nits." Mention is also made of the fact that when lethane was used for the treatment of a group of 8,746 cases only 0.916% of failures was noted, the criterion for failure being the finding of *live lice* from one to three weeks after treatment.

Similar experiments were tried in Liverpool, but it will be noted that the criterion for failure in the Liverpool experiments was the finding of *live larvae* from one to three weeks after treatment. This difference in standards may account for the big discrepancy in the percentage of failures recorded in the two series of experiments. The Liverpool experiments were carried out in two remand homes and one city hospital, where the opportunities for reinfestation were practically negligible. As against the previously reported 0.916% of failures 35% of failures was recorded—i.e., live lice were found, at some time or other, one to three weeks after treatment. Almost invariably the lice found in these cases of failure were very diminutive in size, looking like specks of dust, yet on magnification they proved to be larvae. In the Liverpool experiments these were found mainly as the result of the nurse who carried out the experiments teasing out the combings on a piece of paper and examining them with a magnifying glass. It is suggested that the small percentage of failures encountered in the experiments quoted in the memorandum may be due to these small larvae having been missed by the naked eye of the observers.

The Liverpool experiments fully confirmed the fact that lethane was lethal to lice, but the big percentage of failures recorded can only be attributed to the fact that the lethane was not lethal to the nits, because in most of the cases the heads were inspected daily after the lethane application and adult lice were never found, only young larvae, some days up to three weeks later. Obviously these must have hatched from the nits which had purposely been left behind and had not been killed by the lethane. That lethane did not act as a preventive for killing the newly hatched larvae for more than a day or two was shown by the number of instances in which live larvae were found a few days after its use. It is possible that on exposure to air lethane loses its potency through volatilization of its lethal factor. That lethane does possess a volatile factor was shown by the fact that when lice were placed in vessels at the bottom of which were a few drops of lethane with which the lice could not come into contact they always died within an hour or less.

Considerable experience at a camp school has elicited the fact that complete disinfestation of heads by combing alone is by no means always successful. Various experiments, therefore, have been continuously tried for the past twelve months with the object of finding some modification of the lethane treatment which would devitalize any nits that might be, and often are, inadvertently left behind after combing. In my opinion this factor is at least equally responsible with "home reinfestation" for causing relapses after treatment by combing with a fine-toothed steel comb.

Without going into the details of the various experiments referred to, the latest to be tried might with advantage be recorded, in the hope that others will try out the use of lethane alone and the following suggested modification. The hair is first saturated with a 2% solution of lysol at a temperature about 104° F. After this lysol treatment the hair is combed by the usual methods for the removal of lice and nits. (It was found that the hot lysol treatment greatly facilitated the removal of the nits from the hair.) After combing, the hair is treated with lethane in the manner advocated in the Ministry's pamphlet.

Up to the present ninety cases have been treated by this method and subsequently followed up for three weeks. In not one single instance was any further evidence found of infestation. Cold lysol followed by lethane was not so effective; it showed 10% of failures. Both the lysol solution and the lethane can be very irritating to the eyes, which during treatment should be protected by means of cotton-wool pads. If the experience of others confirms the fact that the preliminary treating of infested hair with hot lysol does succeed in destroying the nits, a further step forward in combating the head lice problem will have been achieved.—I am, etc.,

Liverpool. R. GAMLIN.

Scabies

SIR,—The question of recurrence in this complaint does not seem to have received the attention it merits. After reading various contributions to medical journals on this subject, one is led to imagine (did one not know better) that about two or three applications of certain medicaments will settle the problem in individual cases, and should a recurrence occur, or, rather, should itching persist, this is put down to the residual irritation that follows for a time after a cure.

The fact remains that some individuals appear to have skins which are resistant to the two common remedies—sulphur and benzyl benzoate. After an apparent cure the trouble starts again, even though, within the limits of their means, they have been careful about changing their underclothes and bed-clothes. There is another type of patient, not so careful about personal hygiene, who often has a persistence of scabies around the wrists, and one looks askance at those moth-eaten fur coats and not-so-clean overcoats. How is one to ensure a disinfestation of this kind of garment? For, if it is true that clothes act as fomites, it is probable that the tenacious hold which the acarus gets to the edges of the sleeves is responsible for keeping up the infection at the wrists.

Relatively, treatment of scabies in the Services must be a simple problem, because the medical officer can have his wishes carried out, whereas in civil practice one has to contend with all kinds of difficulties in the home. Scabies, therefore, in an industrial practice continues to be the vexatious problem that it is to-day, and in some cases much time is lost from work. To this must be added the loss of sleep and serious debility suffered by children, who are also afflicted on quite a considerable scale.

The time seems to be due to make scabies a notifiable disease, and municipal clinics should be established for treatment and education of the public as to how to avoid scabies, and what to do themselves when they contract it. This is perhaps a counsel of perfection, but it would at least be a start in the right direction.—I am, etc.,

Hove. G. L. DAVIES.

Abdominal Rigidity in Blast Injuries

SIR,—Lieut.-Col. Denham Pinnock and Lieut.-Col. Paul Wood (May 1, p. 537) stress the extreme difficulty which may arise in differentiating between upper abdominal rigidity due to peritonitis and that secondary to a thoracic lesion. There is one diagnostic trick which I have found may sometimes be of great help in distinguishing such a condition as pleurisy on the one hand from, say, a perforated ulcer on the other. Rigidity due to peritonitis will generally tend to diminish on respiration. If, however, the rigidity is of thoracic origin, it will often be found that there is a definite relaxation of the upper abdominal wall when the patient is told to hold his breath, with his mouth open, at the end of expiration. This sign is sometimes enough to turn the scales when deciding whether or not to perform a laparotomy.—I am, etc.,

STANLEY C. RAW.

Collapse Therapy

SIR,—We have read with interest Dr. W. D. W. Brooks's suggestion that many patients with early pulmonary tuberculosis could be treated with an artificial pneumothorax and then discharged after only a short period of institutional treatment. We are in sympathy with this as a wartime expedient (and it was on account of the shortage of accommodation for the tuberculous that Dr. Brooks put forward the idea), provided the place which the A.P. holds in the treatment of the disease is fully realized.

The A.P. has never yet and never will cure phthisis. A cure can only be attained by the patient developing resistance to the disease, and this is brought about by such constitutional remedies as rest (mental and physical), good food, and fresh air—in fact, all which is embodied in the term "sanatorium routine." The A.P., by placing the lung in the best possible condition for healing, is an adjuvant only in the control of toxaemia and the spread of disease, and assists considerably in the mechanical closure of cavities. Nevertheless, as Dr. P. Heffernan has intimated (May 8, p. 581), success ultimately depends upon the building up of the individual resistance.

We have both had experience of the "peripatetic" A.P., and have occasionally been urged by patients to adopt this method because they were unable, for domestic or financial reasons, to undergo a full course of orthodox sanatorium treatment. We have not been impressed with the results; recovery in such patients has seemed slower and more uncertain and the incidence of effusions higher. Dr. Brooks's suggestion should only be acted upon in those early sputum-positive cases in which activity is minimal—i.e., absence of constitutional symptoms and only a slight increase in the B.S.R.—and we believe that with this proviso the number of patients who can be safely treated in this way will be disappointingly small.—We are, etc.,

London, W.1.

H. V. MORLOCK.
N. L. RUSBY.

SIR,—May I be allowed to endorse the warning given by Dr. Gregory Kayne (April 24, p. 519). He urges that the patient with an artificial pneumothorax may properly be treated as an out-patient only when he has been stabilized in a sanatorium, and shows, from recent American experience, that neglect of this proviso leads to an increased incidence of empyema. The incidence of empyema in A.P. cases, even under institutional conditions, is higher than one might suppose. When examining published statistics I found a total of 284 empyemata in 2,646 cases, a percentage of 10.7 (*Lancet*, 1939, **1**, 134). It seems likely that the figure is higher rather than lower in unpublished cases. The long and disheartening course of tuberculous empyema, and its frequently fatal termination, make it a complication to be avoided. "The average mortality for published cases, then, was approximately 50%. One must not suppose, however, that the remaining patients were cured. On the contrary, many were classed as 'improved,' which meant that they died slowly. . . . And no doubt the mortality for unpublished cases would be greater still."—I am, etc.,

Westminster

LAWRENCE ROBERTS.

Test of Resolution and Endurance

SIR,—Dr. Harper believes that the 40-mm. test may be regarded as an indication of the resolution and power of endurance of the subject and/or his physical fitness, and Sir Adolphe Abrahams has doubts. It may, therefore, be worth while to record the results of this test, performed at sea-level, on twelve men who afterwards climbed high on Mount Everest. The highest camp reached by each climber may be taken as a good index of his physical fitness, for each man climbed to the greatest height of which he was, in my opinion, at the time capable. In only one instance was I not present to give an opinion.

Highest Camp Reached	No. of Climbers	40-mm Test	
		Range	Average
VI (27,400 feet) .	6	50–90 seconds	70 seconds
V (25,700 ") .	2	75–75 "	75 "
IV (22,700 ") .	4	58–90 "	77 "

I am not suggesting that these figures are of great significance, but they may be of interest, and I record them for what they are worth.—I am, etc.,

Whitchurch, Bucks

RAYMOND GREENE.

Irritant Spectacle Frames

SIR,—In December, 1927, the late Dr. R. W. MacKenna of Liverpool treated a patient for spectacle dermatitis such as described by Dr. H. Thistlethwaite (April 17, p. 493). It was the first case he had seen, and he referred to his colleagues in London, none of whom had seen a case. Shortly after that date Dr. Elizabeth Hunt told me of an article which had appeared in an American journal describing the condition and showing how an outline inflammation was produced on the arm by binding the frames on to the patient's arm. Since 1927 Dr. MacKenna's patient has been supersensitive to anything with black or brown dye—e.g., gloves or clothing.—I am, etc.,

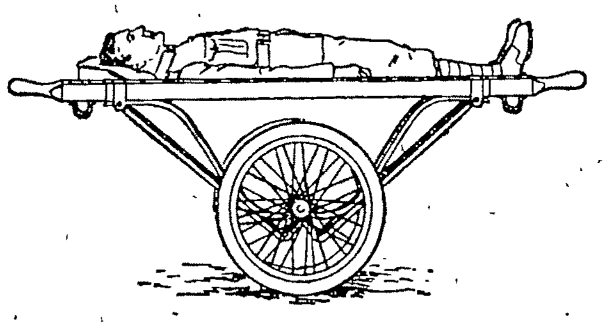
Aberdeen

W. M. GRAY.

A Wheeled Stretcher or Equipment Carrier

SIR,—Your correspondent Dr. K. Vernon Bailey (May 1, p. 542) is probably not aware that a wheeled stretcher carrier was in use by the British Army during the war of 1914-18 and with slight modifications is still being used. This official stretcher carrier has stood the test in war; it is capable of withstanding very rough handling and is of simpler construction than the model described by your correspondent. The fact that it is designed to carry only one stretcher is considered an advantage on active service.

The "Miller-James" collapsible stretcher carrier has a folding collapsible frame. The axles are jointed so that the two wheels can be brought close together and the apparatus easily transported. Running up from the axles at each side are two elliptical springs, on the top four corners of which the stretcher is supported. The tyres are pneumatic, of broad tread, and consequently do not sink deeply in firm mud, but offer great resistance when forced through liquid mud.



—I am, etc.,

The War Office.

C. A. WHITFIELD,
Lieut.-Col.

Doctors and the Future

SIR,—We have been unable to find any concise statement of the evidence on which the agitation for the drastic and immediate changes in the conditions of medical practice is based. The agitation suggests a general feeling that something is radically wrong with our present methods and that patients do not get proper and efficient treatment. Is such a feeling really widespread, and, if so, how has it arisen?

If it is justified by facts it is apparent that a serious effort must be made to remedy the proved defects, bearing in mind that it takes some time to assess the value of any new form of treatment. If it is of the nature of a panacea envisaged by idealists it deserves respect and, possibly, consideration. If it is merely a nostrum exploited by political hucksters it might justly excite resentment.

The production and publication of evidence in a form that could be readily digested by busy doctors would be of incalculable value, not only to them and to the younger men serving with the Forces, who, after all, are those most affected by the proposed changes, but to those, less actively engaged in professional work, who have time to decide the future of medicine.—We are, etc.,

A. BASIL ROOKE. C. E. P. MARKBY.

D. D. MALPAS.

Royal Victoria and West Hants Hospital, Bournemouth.

Chairs of Child Health

SIR,—I am glad that Prof. Sydney Smith has corrected the mistake that the University of Durham was the first university in the kingdom to establish a chair of child health, and has pointed out that Edinburgh took this step more than 10 years ago. This gives me the opportunity of paying a tribute both to that university and to the University of Glasgow. There was a time when each of these Scottish universities was spending more on their departments of child health or paediatrics than all the English universities and medical schools put together.

How heartily I agree with Prof. Smith when he says that what matters most, however, is that these departments should now be established in our universities! The promotion of health and the cure of disease in children are not subjects of minor clinical importance.—I am, etc.,

Newcastle-upon-Tyne. J. C. SPENCE.

Obituary

W. J. EASTWOOD, M.Ch., F.R.C.S.Ed.

Brigadier, A.M.S.

The death of William James Eastwood at the early age of 40, on service with the Army of the Middle East, has brought an end to a short but brilliant surgical career. During his education at Merchant Taylors' School and the University of Liverpool, Eastwood held a high position both in the scholastic and academic fields, playing rugby football and running for his school, university, and county.

After graduation he decided to devote himself to orthopaedic surgery, in which his skill has since been recognized internationally. His contributions to surgery were few in number, but what they lacked in quantity was compensated by the clarity of writing and soundness of opinion. He had a peculiar gift for teaching both the undergraduate and the graduate, who recognized his determination to concentrate on principles rather than on details. He was attached as orthopaedic surgeon to the Northern Hospital in Liverpool, while his work at Alder Hey Children's Hospital and the Wigan Infirmary gave him the breadth of clinical experience on which his skill was based. Joining the Army two years ago he rose rapidly to the rank of brigadier, to which he was officially posted a few weeks before his death. His work as consulting surgeon in the Middle East was characterized by great organizing ability, tact, and surgical skill, and to him is due much of the improvement in results of the surgery in that area.

In his personal contacts Eastwood was particularly happy, being kindly and helpful to those of his staff, and always willing to discuss their problems and help in any difficulties. Those of us who had the privilege of his friendship will remember him as a true friend, who seemed to be constantly bearing his own and other people's burdens.

T. P. McM.

W. BREMNER HIGHET, F.R.C.S.

The death of Temp. Lieut. William Bremner Highet, R.A.M.C., was announced at a meeting of the Royal College of Surgeons of England on Feb. 11. In July last he was elected a Hunterian Professor to deliver two lectures on injuries to peripheral nerves. He was born on April 10, 1911, was educated at Otago, and graduated M.B., Ch.B. of the University of New Zealand in 1934. He was elected F.R.C.S. in 1938. After filling a post at the Dunedin Hospital he came to England in 1935 and held house appointments at the Dreadnought Hospital, the Princess Beatrice Hospital, the Royal Cancer Hospital, and the Norfolk and Norwich Hospital in turn. He obtained the Nuffield scholarship in orthopaedic surgery in April, 1940, and then became first assistant in the Nuffield Department of Orthopaedic Surgery (Peripheral Nerve Injury Centre) at Oxford, a post he held until he entered the R.A.M.C. in Sept., 1942. In 1941 he was awarded the Jacksonian Prize of the Royal College of Surgeons of England for his essay on "Injuries to Peripheral Nerves, with Special Reference to Late After-results," and he contributed a paper on "Splintage of Peripheral Nerve Injuries" to the *Lancet* of May 9, 1942. He had been a member of the B.M.A. since 1934.

We are indebted to Prof. G. R. GIRDLESTONE for the following appreciation.

William Bremner Highet, to the great sorrow of his many friends, has been missing at sea since Dec. 6, 1942, and it must be presumed that he is lost. He was 31 years of age, and was born in Dunedin, New Zealand. He took his M.B., Ch.B.N.Z. at Otago University, where he was awarded Junior National, Senior National, and University National Scholarships. He held house appointments at Dunedin Hospital, and in 1935 went with the second Byrd Antarctic Expedition as medical officer. Afterwards, before coming to England, he spent three months visiting hospitals in the U.S.A. From October, 1935, to 1937 he held resident posts at the Norfolk and Norwich Hospital, and while resident orthopaedic officer there became deeply interested in orthopaedic surgery and decided to devote himself to it. He was subsequently R.S.O. at the Princess Beatrice Hospital, where he had charge of the fracture clinic and inaugurated a septic finger clinic. From the outbreak of war until April, 1940, he acted as surgical registrar at the Royal Cancer Hospital, where he made a thorough study of bone tumours. In April, 1940, he joined the staff of the Wingfield-Morris Orthopaedic Hospital, Oxford, having been appointed Nuffield scholar in orthopaedic surgery. The creation of the peripheral nerve injury centre later in the same year was followed by such an influx of cases that it soon became necessary to appoint a man who could devote all his time to work on nerve injuries. Thus at the end of 1940 Mr. Highet ceased to be Nuffield scholar, and was given a special research grant by the University. He assisted Prof. Seddon in the scientific study of the rate of regeneration of nerves. He developed a technique for the investigation of anomalous innervation of muscles and cutaneous areas, and in particular investigated the part played by the ulnar nerve in the innervation of the thenar muscles, and his findings have cleared up certain anomalies which had previously been encountered in some cases of total median thenar loss. In collaboration with Prof. Seddon he investigated the effects of post-operative stretching of nerves, where much loss of the nerve had necessitated the flexion of one or more joints; he also joined in research on certain ischaemic lesions which were found to be attributable to arterial spasm rather than to the original injury.

In 1942 Mr. Highet was awarded the Jacksonian Prize of the Royal College of Surgeons for an essay on peripheral nerve injuries. He gave himself unsparingly to the study of peripheral nerve injuries and their operative treatment, and, spending long days in this most exacting work, mastered his subject. The victims of nerve wounds often suffer from severe disabilities which drag on for many months, and may need repeated operation. Many such men found in Mr. Highet both operative skill and personal encouragement, for he proved himself a good doctor and a good friend. He was on his way to similar work for the Forces over-seas when he lost his life.

His colleagues learnt to appreciate his high qualities, which were associated with a fundamental integrity and modesty, more and more as they worked with him. His death is a very great loss to us and to the whole fellowship of orthopaedic surgeons. To Mrs. Highet and her child we extend our deepest sympathy.

Supplementing our obituary notice of Mr. C. Lambrinudi (May 15, p. 617) Sir Arthur Hurst writes: Some ten years ago Lambrinudi had a long and almost fatal illness which left him liable to sudden death at any time. He well knew this and the danger of overwork, but he never allowed it to interfere with the long hours he put in at the service of his patients at Guy's and in private, for his great skill had naturally brought him a large consulting practice. The hospital, however, always came first, and he looked forward to devoting all his energies to the service of his beloved Guy's after the war. Always cheerful and the best of company, he told me in a letter written within a month of his death that he had accommodated himself to living from day to day without fear of the future and enjoying every minute. He will be sorely missed by his many devoted friends and his innumerable grateful patients, who will all wish to extend their sympathy to his wife, son, and daughter.

Dr. G. Douglas McRae, who died in Edinburgh on May 7, aged 68, was well known as a psychiatrist. He graduated M.B., C.M.Ed. in 1895 and proceeded M.D. with honours in 1907, in which year he was elected F.R.C.P.Ed. Dr. McRae took up the study of mental disease not long after graduation, and was for a time assistant medical officer at the West Riding Asylum, Wakefield, and then assistant physician and pathologist at the Royal Morningside Asylum. His last appointment was that of physician-superintendent at Glengall Hospital, Ayr. He served as president of the Royal Medico-Psychological Association in 1937–8 and had been joint editor of the *Journal of Mental Science*. He joined the British Medical Association in 1897 and held office as president of the Glasgow and West of Scotland Branch in 1923. He was also a member of the Edinburgh and the Glasgow Medico-Chirurgical Societies.

Capt. G. N. Braham, F.R.C.S., died in Baghdad on Nov. 16 and an obituary notice appeared on Dec. 12, 1942 (p. 710). A colleague writes: Dr. Braham's work as a surgeon in Iraq will be looked upon with great respect by British and Iraqis for a long time to come. His great virtues as a surgeon were his sound judgment, careful handling, and avoidance of meddlesome surgery. He was an excellent practical teacher, a good clinician, and a skilful operator whose cases did well. He had very good hands and had the art of imparting his skill to others, being patient and very helpful to his assistants who were training under him. At the same time he was fearless in his expression of opinion on medical matters and was a great asset to the Council of the Medical School. He was very generous to all who sought his advice on any problem and it was most sound. He had a profound understanding and sympathy for the country to which he gave much of his work and did much to promote harmony.

The following well-known medical men have died abroad: Dr. Edward R. Maloney, emeritus professor of dermatology at New York University College of Medicine and consulting dermatologist to the Bellevue Hospital, New York, aged 68; Dr. David King Smith, formerly president of the Toronto Academy of Medicine and member of the British Association of Dermatology and Syphilology (Canadian Branch), aged 69; Dr. Aaron Joshua Rosanoff, professor of psychiatry at Los Angeles and associate editor of the *American Journal of Psychiatry*; Dr. Edgar Allen, professor of anatomy at Yale University School of Medicine, aged 50; Dr. Ewing Wilber Day, past-president of the American Otological Society and emeritus professor of otology, laryngology, and rhinology at the Pittsburgh University School of Medicine; Dr. Jean Louis Burckhardt, director and founder of the Children's Sanatorium at Davos, formerly lecturer on hygiene and bacteriology at Basle University; and Prof. Georg Magnus, director of the Surgical Clinic at Munich and coeditor of the *Münchener medizinische Wochenschrift*.

Among recent arrivals in this country from the U.S.S.R. is Prof. S. A. Sarkisov, who represents the Soviet Red Cross and Red Crescent, and who is exchanging with experts here new knowledge gained in the treatment of wounded and sick and in rehabilitation. Prof. Sarkisov was born in 1895, and in 1926 helped to organize the Moscow Brain Institute. He has published over 30 works on neurology and psychiatry, and is a member of the administration of the Soviet Society of Neuropathologists and Psychiatrists, of the Soviet Society of Physiologists, and of the Neurosurgical Council. Since 1937 he has been vice-president of the Scientific Medical Council of the U.S.S.R., of which N. N. Burdenko is president. This council forms a very important part of the medical organization of the U.S.S.R.

Medical Notes in Parliament

Mr. Johnston, in the House of Commons on May 6, introduced the Nurses (Scotland) Bill to make provision in Scotland for the enrolment of assistant nurses for the sick, for the restriction of the use of the name or title of nurse, and for the regulation of agencies for the supply of nurses for the sick, and to amend the Nurses Registration (Scotland) Act, 1939. The Bill was read a first time.

Positive Health in the House of Lords

A debate on the health of the people was opened in the House of Lords on May 5 by Lord Geddes. He said that during the evacuation from the great towns in 1939 he had been impressed by the listlessness of the young people and adults from the crowded areas of the cities. Their physical condition was better than when he was a young doctor, and signs of rickets were absent, but a great deal of their independence seemed to have vanished. He had noticed a similar contrast between the conscripts of this war and the young men who served in 1914 or in the Boer War. This Easter he had seen some of the children still evacuated and they were grand. They were entirely different young people. Adults and elder children who came to the country in 1939 and 1940 were to a surprising extent convinced that they were not well. They all seemed to believe that patent medicine was an essential element of diet. In the cities and even in Government offices people had been infected in the cult of negative health and thought that they ought always to be taking medicine. The term "positive health," which had been used in the report of the B.M.A. on the organization of the medical profession, had a special meaning. It meant that you were not going to be ill. The whole tendency of the medical profession was to deal with people by giving them tablets out of a bottle or fluid in a bottle. That must be so under present conditions, and would be worse under a State Medical Service. To be well without taking anything was what positive health meant. A certain amount was done for positive health by a section of the medical profession, and a good deal by the Ministry of Food, but ideas on it were vague. Importance was attached to measurable things like height and weight. But large size was not necessary to high efficiency. There was as yet no science of positive health. There was no knowledge whether a child was benefited by being given large quantities of milk between 11 and 13 years. It grew larger, but there was evidence to show that men of larger sizes and larger bulk were dying younger. The death rate was rising in the 50–65 period, which showed something was wrong in the general life of the individual. Positive health meant that the body of each man, woman, and child should have power to resist the assaults of the pathogenic bacteria. These resistances should be natural. Science in medicine at present laid an undue emphasis on the attackers and too little on the defence of the human body. Alexis Carrel had suggested there should be in each of the great countries a "General Staff of Health," to advise the Government on social legislation affecting health. Such a general staff would perhaps report to the Government through the Lord President of the Council. It would not be a research body, but would collect results of research.

Lord Snell, replying for the Government, said the present medical services would stand comparison with any in the world. But these services tended to be piecemeal and restricted in their scope. The Government had laid on local authorities a statutory responsibility for planning comprehensive hospital services on the basis of wide areas and of division of function between hospitals. The post-war policy must include the position of the general practitioner. Thousands of young doctors were away on war service and had the right to expect conditions when they returned which would give them an honoured and useful place in their profession. The Government had accepted the principle of a national health service which would meet the needs of every citizen. In a few months a general statement of the Government's proposals would be published. There was no need to be unduly depressed about the conditions revealed by the evacuation.

Lord Geddes said the reply of the Government confirmed his impression that what was meant by positive health was not fully appreciated.

Government's Proposals for Health Services

Sir Percy Hurd asked on May 6 whether steps will be taken to enable medical men and women and nurses serving with the Forces abroad to express their views in the discussions now proceeding on the future of medical and health services. Mr.

BROWN replied that he contemplated publishing as soon as practicable a statement of the general nature of the Government's proposals, which would enable everybody (including men and women in the Forces) to see for themselves what was suggested and to discuss and, if necessary, criticize before the stage of legislation was reached.

Osteopathy

On May 6 Mr. BAXTER asked the Minister of Health if there was any likelihood of his changing his attitude towards osteopathy in wartime, and if it was his intention to recognize osteopathy as a legitimate branch of medical science. Mr. Brown replied: No, sir. It is not my intention to propose any amendment of the law on this matter.

Rehabilitation Treatment for Civilians

Mr. GRANVILLE on May 4 asked the Minister of Health if he would consider providing rehabilitation centres for sick and injured artisans analogous to those provided for the Services, to be worked by, or in conjunction with, factory medical officers. Mr. ERNEST BROWN replied that rehabilitation treatment of the kind referred to was already being provided at or in connexion with a number of hospitals under the E.M.S. scheme, and medical officers of his Department were at present visiting all the larger hospitals in each region to discuss with the hospital authority methods of developing such provision. He understood that the Minister of Labour had decided to set up an experimental centre for certain types of cases needing rehabilitation beyond the stage to which it could reasonably be provided as part of the hospital services, and that he had under consideration the question of extending the experiment in accordance with the recommendation of the Interdepartmental Committee on the Rehabilitation and Resettlement of Disabled Persons.

Domestic Staff of Nursing Homes.—The Minister of Labour and National Service has instructed his local officers not to withdraw domestic staff in nursing homes except after consultation with Regional Officers of the Ministry of Health and with their consent. Mr. Brown has instructed his Regional Officers to consider each case on its merits, and if a particular nursing home is an essential part of the area's hospital facilities, to advise that it should be treated on the same lines as a hospital, so that the domestic staff there would all be reserved. If, however, there are redundant staff by hospital standards agreement would be given to withdrawal of the redundant workers.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on May 6 the following medical degrees were conferred:

B.M., B.CH.—M. J. Long, R. Patuck, *J. C. H. Dunlop, *G. K. H. Hodgkin, *D. M. de R. Winser, *L. E. D. F. Joubert, *D. H. Garrow, *G. D. W. McKendrick, *E. H. Hillyard, *T. H. J. Williams, *Sheila R. Tangye

*In absence.

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council held on May 14 Mr. J. T. Chesterman, F.R.C.S., was appointed lecturer in surgical pathology and assistant curator of the museum.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of Council on May 13, with Sir Alfred Webb-Johnson, President, in the chair, Mr. J. B. Hume was re-elected a Member of the Court of Examiners for the period of one year from June 10, 1943, and Prof. R. V. Bradlaw was elected a Member of the Board of Examiners in Dental Surgery for three years from June 10 next. It was decided to recognize the post of resident surgical officer at the Guest Hospital, Dudley, for the six-months surgical practice required of candidates for the Final Fellowship Examination. Mrs. H. P. Herbert, B.A., was appointed a Leverhulme Scholar for the year beginning May 10, 1943, for her research on the metabolism of proteins, especially in relation to their protective properties against disease. Mr. Arnold Sorsby, F.R.C.S., was appointed Research Professor in Ophthalmology at the Royal College of Surgeons of England and the Royal Eye Hospital for the period of five years from July 1, 1943. A Professorship in Experimental Pathology was conferred upon Dr. W. E. Gye, F.R.S., Director of the Imperial Cancer Research Fund. Prof. Gye and Mr. H. G. Crabtree were appointed Lecturers of the Fund in the College for the ensuing year. Group Capt. G. L. Keynes was nominated external examiner in surgery for the Fellowship examination of the Faculty of Radiologists.

Diplomas of Membership were granted, jointly with the Royal College of Physicians, to the candidates whose names appear in the report of the meeting of the Royal College of Physicians published in the *Journal* of May 15 (p. 618), and to Sheila W. Anderson, G. A. James, and M. F. C. Walker.

The Services

A *Supplement* to the *London Gazette*, dated May 14, announces the appointment to O.B.E. (Military Division) of Acting Squad. Ldr. Frederick Thomas Moore, F.R.C.S., R.A.F.O., and the award of B.E.M. to Leading Aircraftman B. V. Icke. One night in March, 1943, an aircraft crashed on an R.A.F. station and immediately burst into flames. Squad. Ldr. Moore (the duty medical officer) saw the accident and, accompanied by L/A Icke, a medical orderly, proceeded to the scene. Squad. Ldr. Moore directed the removal of the rear gunner, who was dazed and sitting amongst the burning wreckage, to a place of safety. The aircraft was now enveloped in flames and ammunition was exploding. Nevertheless, despite the intense heat and the danger from exploding oxygen bottles, this officer and airman entered the burning wreckage in an attempt to rescue another member of the crew who was pinned down. Without any protective clothing they lifted aside the burning wreckage and, with great difficulty, succeeded in extricating the injured man. Squad. Ldr. Moore rendered first aid to the rescued man and sustained burns to his chest and hands in carrying out the operation. This officer and airman both displayed courage and devotion to duty in keeping with the highest traditions of the Royal Air Force.

CASUALTIES IN THE MEDICAL SERVICES

Prisoner of War in Japanese Hands.—Capt. M. F. Smith, R.A.M.C., Cambridgeshire Regt.

Died.—Lieut. Sheila Dorothy Markham Brown, R.A.M.C.

Medical News

A paper on identification of animal fibres will be read by Dr. J. L. Stoves before the Medico-Legal Society at 26, Portland Place, W.1, on Thursday, May 27, at 5.30 p.m. Members may introduce guests to the meeting; tea at 5 o'clock.

At a meeting of the London and South-Eastern Counties Section of the Institute of Chemistry, to be held at 30, Russell Square, W.C., on June 16, at 6 p.m., Dr. W. T. J. Morgan of the Lister Institute will lecture on "Some Recent Advances in Immuno-chemistry."

An opportunity for Roman Catholic doctors to discuss future medical services is being provided by the Sword of the Spirit Movement at a meeting to be held in the Essex Hall, Essex Street, W.C.2, on Saturday, June 5, at 3 p.m. The subject is "Catholics and the Future of Medical Services" (Assumption B of the Beveridge report), and the speakers will be Dr. Charles Hill, Dr. E. E. Larkin, and Dr. Letitia Fairfield.

A special film session for doctors has been arranged by the Bristol Medical Officer of Health in collaboration with the Ministry of Information to take place at the Odeon Cinema, Union Street, Bristol, on Sunday, June 6, at 10.45 a.m. Two films will be shown: "Scabies"—the new film just issued for the Ministry of Health—and "Neuropsychiatry." An address on "Scabies—a Present Problem" will be given by an assistant medical officer, Bristol Health Department. Doctors will be admitted on presentation of their professional cards or by the invitation folder available on application to the Bristol Public Health Department, Kenwith Lodge, Westbury Park, Bristol, 6.

A meeting of the executive committee of the Cancer Control Organization for Edinburgh and South-East Scotland, the objects of which include the investigation, care, and cure of cancer, was held in Edinburgh recently. Among the subjects discussed was the fuller use by medical practitioners of the system of the organization whereby practitioners may arrange for the issue of travel vouchers to enable persons suffering or suspected of suffering from malignant disease to attend at Edinburgh Royal Infirmary for treatment or for examination. The honorary treasurer of the organization is Prof. William Annan, C.A., 22, Charlotte Square, Edinburgh, to whom subscriptions, donations, or bequests by way of legacy should be sent.

The U.S. Office of War Information announced on May 10 the formal opening of the American Library, which has been operating for several months as a special reference library at the American Embassy, 1, Grosvenor Square, W. The library is designed for American, British, and other United Nations' officials, agencies, for research institutions, associations, business, and for the Press. The American Library Association, the Library of Congress, learned societies, and many other American associations, and their opposite numbers in Great Britain, have been consulted constantly in building up this modest but potentially important centre and cultural focus.

The Treasury has made an Order under Section 20 of the Finance (No 2) Act, 1940, exempting from purchase tax batteries of not less than 30 volts and not more than 90 volts specially designed for high-tension supply for deaf-aid appliances and using cells not larger than 40 mm. over all in length by 13½ mm. in diameter. The exemption applies only to goods delivered on sale or appropriated to retail trade or similar purposes on and after May 11, 1943, or, in the case of imports, to goods entered for home use on and after that date.

Owing to prevailing conditions difficulty is being experienced by the London County Council in filling vacant positions for assistant pathologists in the hospital laboratory service. In order to secure a wider field of candidates it is proposed that a new class, to be designated junior assistant pathologist, should be instituted to appeal to medical practitioners who, although not fully experienced in pathological work, have a bias in favour of this particular branch of the profession. There are to be 17 such positions, the salary to be £500 a year, rising by annual increments of £25 to £575.

The Colonial Office announces that a subcommittee of the Colonial Advisory Medical Committee has been appointed to advise the Secretary of State on the problems of venereal disease in the Colonies Mr. T. I. K. Lloyd, an assistant under-secretary of State in the Colonial Office, will be the chairman of the subcommittee. The members include Sir Wilson Jameson, Sir Drummond Shiels, Dr. Mary Blacklock, Dr. Letitia Fairfield, Dr. Robert Sutherland, and the medical advisers to the Secretary of State.

The Board of Trade announces that the sale and hire of all typewriters, except second-hand portable machines weighing less than 22 lb., are now controlled. No dealers or private individuals may dispose of or acquire typewriters without a licence, and special permission will be required before any machines may be broken up. Applications for licences should be addressed to the Directorate of Office Machinery, Hawkins House, Dolphin Square, S.W.1.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the decline in the notifications of infectious diseases continued, especially for measles 386, whooping-cough 187, scarlet fever 87, and diphtheria 43. Dysentery, however, rose by 66, acute pneumonia by 40, and typhoid by 13.

The rate of decline in notifications of measles was not so marked as previously, notifications falling by 386, compared with an average fall of over 2,000 during the preceding three weeks. The largest decreases recorded during the week were Sussex 118, Warwickshire 115, Durham 113, Cornwall 100, London 90; the largest rises were Glamorganshire 112, Suffolk 80, Berkshire 62, Northamptonshire 52, Hampshire 40. In two counties, Suffolk and Norfolk, the notifications were the highest during the present epidemic.

Within the counties only small variations occurred in the incidence of diphtheria, except in Lancashire and Cheshire, where the incidence has been almost halved during the past five weeks. Diphtheria is still relatively prevalent in the North, and 38% of the week's notifications were in the three counties of Durham, Lancashire, and Yorks West Riding.

For scarlet fever the largest declines were Yorks West Riding 69, Essex 31, and Lancashire 29; and for whooping-cough, London 48, Lancashire 47, Warwickshire 32.

Notifications of dysentery were doubled during the week. An outbreak in Staffordshire, Stoke-on-Trent C.B., 45 cases, was confined to the nursing staff of the North Staffordshire Royal Infirmary. Kent, Maidstone M.B., reported 16 cases, Gloucestershire, Bristol C.B., 14, Lancashire 13, and London 11.

The rise in typhoid from 3 to 16 was due to sporadic cases occurring in nine counties.

In *Scotland* the notifications of dysentery rose from 26 to 65, the highest level of recent months, the chief centres of infection being the counties of Banff 10, Midlothian 10, and West Lothian 15. Notifications of measles fell by 165. Of the two large local epidemics, that in Glasgow showed an improvement, the number of cases falling from 330 to 179; in Edinburgh the number of cases rose from 88 to 104.

In *Eire* the high level of diphtheria incidence, which has persisted since the beginning of January, continued; 37 of the 98 cases were recorded in Dublin C.B.

The Week Ending May 8

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,458, whooping-cough 2,225, diphtheria 643, measles 10,090, acute pneumonia 745, cerebrospinal fever 61, dysentery 193, paratyphoid 7, typhoid 12.

No. 17

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 1.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.) Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

The Negative Phase

Q.—*What is the significance of the "negative phase" following immunization? How long does it take to develop, and how long does it last in the case, say, of A.P.T. and T.A.B.C.?*

A.—When carrying out the active immunization of healthy people against diphtheria and the enteric group under ordinary circumstances, the practitioner may well forget the existence of the concept "negative phase." (At the same time, he must be prepared for the rare "sea-lawyer" type of patient, who, because he has been already heavily infected before vaccination, may develop the disease, and by a *post hoc* line of argument maintain that he is a victim of "negative phase." Anyone who is a member of a medical protection society will face such a contingency with composure.) In the laboratory one could show, by carefully planned experiments, that the immunity of an animal partially immunized against diphtheria or enteric could be temporarily depressed by huge doses of toxin or antigen. It has therefore been argued that where intense exposure has existed—e.g., the drinking of water or milk heavily infected with bacilli of the enteric group—there is a possibility that the injection of T.A.B.C. vaccine might possibly increase the liability to clinical attack in those infected with only a small dose of bacilli. A medical leader writer[1] claimed that such vaccination was a "highly undesirable procedure." This does not seem to be the general view. Discussing the hypothesis that "the administration of vaccine will for the time being lower resistance instead of increasing it, an effect which might be disastrous during the incubation period," a leading article in this *Journal*[2] concluded: "An examination of actual evidence lends no support to this theoretical objection." Sir John Ledingham[3] said that the literature abounds in records of epidemics (isolated or explosive) where vaccination of exposed persons has been put in force as a measure of control without evidence of unfavourable results. With reference to the Portsmouth epidemic, Dr. Facey[4] stated that, in response to inquiries of various authorities, "the general consensus of opinion was to the effect that inoculation was definitely indicated and that the risk of a negative phase could be ignored."

The League of Nations Health Committee[5] in 1932 resolved that "immunization is to be recommended even during epidemics in the case of children who have been in contact with patients, as there is so far no evidence on record as to the existence of a negative phase." It is improbable that a similar international committee would to-day reverse that resolution.

The questioner will find his inquiry discussed at length in the *Journal* in the autumn of 1937 following the Croydon "explosive" outbreak of water-borne typhoid fever. He may also note that, from the birthplace of the "negative phase," Dr. Maclean[6] in 1941 observed: "My own experience has led me to disregard the danger of a negative phase in healthy persons in the presence of an epidemic."

Rough Lips: Infected Nails

Q.—*There are two minor ailments which are constantly cropping up in general practice. The first is a condition of the lips (that part which is commonly rouged), met with in both sexes, where the epithelium is roughened and tags of loose skin appear on the surface. This condition is of course met with in acute illness and chronic disease, but I am mostly concerned with it as found in normal healthy subjects. The second problem is a form of chronic infection in the region of the finger-nails, mostly affecting females and very often near the menopause. One finger after another gets involved and pus wells up from the side of the nails for long periods before a cure is effected.*

A.—A scaliness about the lips, more common in girls and young women than in men, is not infrequently seen in dermatological clinics. When the condition is well marked, chronic fissures are usually present at the angles of the mouth, and the whole picture suggests a vitamin B_2 deficiency, and will sometimes respond remarkably to riboflavin, 1 mg. three times a day after food. (But it should be pointed out that the clinical manifestations of ariboflavinosis are at the moment a matter of dispute.) If the case does not respond to this vitamin alone, it is better to try a compound vitamin of the B group, giving, in addition, ascorbic acid 50 mg. twice a day. Sometimes the scaly condition referred to is part of a seborrhoeic dermatitis, and the scalp should be examined to find evidences of this possibility. If scurf is present, the same vitamin therapy may be given with some advantage, but local applications are important. An ointment consisting of liq. pic. carb. ♏ 30, sulph. praecip. gr. 10 in ung. acid. salicyl. *B.P.*, will be found useful for the scalp, and, if applied very lightly, it may also suit the scaly skin of the face; but if it is not tolerated on the face, then 2% of ichthammol in lotio calamin. oleosa will be a better local application. It must be remembered that cheilitis and a scaly dermatitis about the mouth may result from lipstick or even from something in a tooth paste or perfume to which the patient is allergic, so that the possibility of a dermatitis from an external factor must always be considered.

The second problem seems to be concerned with chronic paronychia, in which mild infections occur at the sides of the nail and may be very chronic and relapsing. Sometimes they are of mycotic origin, but usually are pyogenic. The general condition of the patient should be considered, and a tonic containing iron and arsenic, or a combined syrup of hypophosphites, should be given after meals. Local treatment consists in hot hypertonic saline baths, with gentle massage of the nail folds to express any underlying pus. After drying, the following paint should be applied night and morning to the edge and sides of the nails: phenol. liq. ♏ 10, tinct. iod. mit. ♏ 120, spir. meth. indust. ad oz. 1. When the condition appears to be cured the paint should be applied daily for a further month or two in order to prevent relapses. Frequent washings and employments which keep the hands continually wet (e.g., in a barmaid) render the skin folds about the nails very susceptible to infection, so that in relapsing cases it may be necessary to effect a change of employment. In dermatological clinics doses of *x* rays are very helpful in the treatment of the difficult cases.

Hypertrophic Mastitis

Q.—*A well-built girl of 21 has been suffering for some 3 to 4 months from what I believe to be a subacute mastitis. She has rather heavy breasts, and the lesion has been a tender diffuse lump in the upper lateral quadrant of each breast, more pronounced in the left one. I ordered a firmly supporting brassière, and ultra-short-wave therapy was tried for a period, together with rest. She is a land-girl whose main occupation is milking. There was some improvement, but now she gets a severe relapse with the approach of menstruation. Would any form of hormone therapy be beneficial, since menstruation seems now to be the most aggravating factor? Her menses are fairly normal except that the interval between is sometimes slightly shorter than usual.*

A.—The condition is probably a so-called hypertrophic mastitis, predisposed by some slight hormonic disturbance and determined and localized by trauma due to the pressure of a light brassière or to her work. The term "mastitis" is really a misnomer, because it is likely that the changes are due to an exaggeration of the normal cyclical activity of the breast with menstruation. The hormonic control is only partially understood, and so it would be wise to try other methods of treatment before resorting to hormone therapy. Superficial *x*-ray exposures will often relieve the pain and tenderness; or, if available, radio-active pads (usually containing mesothorium), which are worn for a few days continuously, may be tried. The successful use of hormones in older women, especially those about the climacteric, does not indicate that they would be equally valuable in a case of this type.

Premature Ejaculation

Q.—*What is the best line of treatment for a premature ejaculation which prevents effective penetration being achieved? There is no evidence of organic or psychological abnormality in either partner.*

A.—The treatment of ejaculatio praecox is one of the most difficult that can be undertaken. Previously it was treated mainly by physical remedies—instillations into the posterior urethra of silver nitrate, light scarification of the verumontanum with a diathermy electrode, etc. Now it is generally believed that psychological rather than physical factors are responsible for the condition. It occurs usually in sensitive, anxious men and is amenable to psychological treatment. This has usually to be prolonged and should be carried out by an expert.

Arthritis and Intestinal Streptococci

Q.—*I have a patient with chronic infective polyarthritis, presumed to be due to intestinal infection with haemolytic streptococci, large numbers of these organisms being found in the stools. Is succinylsulphathiazole likely to be an effective intestinal disinfectant in this infection, and, if so, what are its toxic reactions?*

A.—It is extremely rare to find haemolytic streptococci in faeces except those belonging to Lancefield's Group D. These organisms have many of the characters of *Str. faecalis*, and share with this variety of streptococcus a high degree of resistance to the action of sulphonamides generally. The proposed treatment is therefore not as hopeful as it sounds, but information available about the action of succinyl-sulphathiazole is not yet detailed enough for a categorical answer to be given. Very little of this drug is absorbed, and toxic reactions from it are negligible. (The " presumption " that arthritis is due to the presence of these streptococci in the bowel may not be correct. Such an association is often assumed but can rarely be substantiated.)

Nasal Drops

Q.—*There is a preparation of ephedrine hydrochloride and argyrol now in wide use as nasal drops in catarrhal infections. Is there any danger in the prolonged use of this, especially in the case of children? The silver is, I believe, retained. What knowledge is there of any ill effects due to prolonged habitual use of benzedrine (or methedrine) nasal inhalation in chronic nasal cases?*

A. Ephedrine is a useful vasoconstrictor for the swollen mucosa in acute inflammatory attacks, and argyrol acts as a demulcent and antiseptic. Where there is an inclination to use astringent applications more than temporarily the swelling is probably in the nature of a vasomotor rhinitis and allergic in character, and therefore other treatment following suitable investigation is indicated. Silver has to be ingested for a long time to cause argyria, but some local staining may be produced more easily. Sollmann (*Manual of Pharmacology*, 1942) states that " many cases have been reported from the routine use of colloidal silver preparations, especially by the laity as prophylaxis against colds generally in children and young people."

Benzedrine also acts as a vasoconstrictor, but is more potent and causes dryness of the mucous membrane. The same criticism applies to its use, and any application which is employed constantly should be in the form of a warm saline solution in water.

INCOME TAX

Appointment—Deduction of Tax—Car Allowance

" **Delta** " began work as assistant M.O.H in June, 1941. His earnings for the period June, 1941, to April, 1943, were assessed somewhat late and the tax deducted during the period November, 1942, to April, 1943; tax on the earnings of the year to April, 1943, is being deducted over the period November, 1942, to October, 1943. He has a car allowance of 4d. per mile, but owing to the petrol shortage this amounted to only £35 for the year to April, 1943. The car cost £130 when bought second-hand in June, 1941.

⁂ (1) The tax appears to be correctly assessed For 1943–4 " Delta " will be assessed on the basis of his earnings for 1942–3, and the tax will be deductible over the period November, 1943, to October, 1944.

(2) The income-tax authorities usually oppose any claim to include an expenses allowance as income and to deduct the actual costs, holding that the employing authority may be assumed to have made an adequate allowance. Where, however, the mileage is relatively small the depreciation by wear and tear may be such as to make the rate of the allowance too low. The " cost " to " Delta," calculated on the usual basis, would be running costs (including petrol, repairs, tyres, etc.) plus the depreciation allowance, which for 1943–4 might be put at, say, £20. It may well be that it would pay our correspondent, therefore, to substitute a cost claim for exclusion of the mileage allowance he received in 1942–3. Whether the point is worth pressing, however, depends on the amount of the running costs. The revenue authorities might oppose a subsequent return to the normal basis of excluding the allowance on the ground that the matter should be dealt with consistently to ensure fairness.

LETTERS, NOTES, ETC.

Prevalence of Pityriasis Versicolor

Dr. **James Hasson** (London, W.2) writes: An epidemic of pityriasis versicolor seems to be occurring at the present time. I have examined several cases and found them true to type with no exception to their peculiarity of resistance to treatment. It will be interesting to know if other dermatologists have noticed an increase in the number of their cases. This " maladie des gueux," as it used to be called by Jeanselme, appears now to be spread amongst all classes.

A New Syndrome ?

Dr. K. **Temple Brown** (University College of the South-West) writes: Referring to Dr. C. E. H. Milner's letter (May 8, p. 590), may I suggest his using a preparation of vitamin B_1 for his patients. This is *the* vitamin with which Nature is frugal, and several cases of symptoms due to its deficiency spring to mind, all within the past two years. There was a french polisher, who had done no work for four months, because of pain in the right upper limb, when he came under my care. Physiotherapy and salicylates had not relieved him, but a course of vitamin B_1 (tablets of 3 mg., 2 tablets t.d.s., p.c.) altered his outlook on life, and in a fortnight he was back asking to be signed off the panel. The cheapest but slowest form of treatment is to use tablets of dried yeast, 4 or 5 gr. Quicker, but more expensive, are the tab. " benerva " (Roche), 3 mg. for oral use, 2 tablets t.d.s., p.c. Most rapid and most expensive are injections of " benerva," ampoules of 25 mg., an ampoule once a week. This is not " blunderbuss " prescribing but diagnosis by a therapeutic test, and quite justifiable.

Dr. **Leonard S. Willox** (Dumbarton) writes: The symptoms complained of by the four patients mentioned are suggestive to me of those that are sometimes found in cases of aluminium poisoning in persons susceptible to the absorption of small doses of aluminium. If the patients are using aluminium cooking utensils or consuming food or drink from any aluminium vessels I suggest that for a fortnight all medical treatment should be stopped, and that the use of aluminium utensils should be entirely abolished. A fortnight will give time to see whether improvement is being made.

Filaria Worm in the Eye

Dr. F. J. **Darbyshire** (Ilford) writes: With reference to recent correspondence about the occurrence and removal of adult *Filaria loa* from the subconjunctiva, I enclose a letter from Dr. T. B. McAleer, whom I asked to record his experiences in the Niger delta. The adult female filaria which I removed from his right eye was easily seen squirming in the subconjunctiva to the outer side of the lower fornix. The eye was cocainized, a piece of conjunctiva picked up gently near the worm and cut by sharp-pointed scissors. The worm obligingly presented in the wound and was withdrawn by forceps. Dr. McAleer's method introduces very little trauma, and, he tells me, was always successful.

Dr. T. B. **McAleer** (Hornchurch) writes: During some years spent in the Niger delta I saw numerous cases of filaria *Loa loa* and removed quite a number of the adult worms from eyes. The technique was simple. The eye was cocainized and the conjunctiva was picked up in small forceps at a point over or near to the worm and, with a small sharp scalpel, an incision was made, about 1/8 in. long, in the membrane. A small hook was then inserted through the opening in the conjunctiva and the worm removed with comparative ease. No sutures were used, and the only antiseptic measure taken was frequent lavage with boric solution before and after the operation. Incidentally I myself have *Loa loa* infection and have had an adult worm removed from my eye in this country by Dr. F. J. Darbyshire of Ilford.

Hand and Finger Lesions

Dr. F. R. W. K. **Allen** (Ernakulam, South India) writes: I agree with all that Surg. Commander J. B. Oldham (Dec. 12, 1942, p. 706) says. The principles of the surgery of the hand and fingers are fully explained in *Surgery of the Hand*, by Marc Iselin. (An English translation is now available.) Since following his methods my results have been excellent, whereas they were often disappointing previously.

Casualties in Rough Country

Lieut.-Col. D. G. **Duff** writes from Denbigh: An article in a current popular picture weekly shows what are presumably the latest Army methods of casualty recovery in rough country as practised in an advanced course of instruction. It is surely regrettable that the lessons of pre-war mountaineering experience have not yet been developed. Axis use of the sledge stretcher, as shown, for example, in a Swiss weekly medical journal of three years ago just sent me by the B.M.A. Library (*Schweizer medizinische Wochenschrift*, 12, 40), must be by now very far ahead indeed.

Keep it Short

The first number of the newly named *British Medical Journal*, dated Jan. 3, 1857, had the following notice to contributors which is worth reproducing in these hard times:

" The Editor would feel glad if Members of the Association and others, would cooperate with him in establishing as a rule, that in future no paper for publication shall exceed two pages of the Journal in length. If the writers of long communications knew as well as the Editor does, that lengthy papers *always* deter the reader from commencing them, this great evil would never arise. Brevity is the soul of medical writing—still more than of wit."

TREATMENT OF PERNICIOUS ANAEMIA WITH AN EXPERIMENTAL PROTEOLYSED LIVER PREPARATION

PRELIMINARY OBSERVATIONS

BY

L. J. DAVIS, M.D., F.R.C.P.Ed., M.R.C.P. L. S. P. DAVIDSON, M.D., F.R.C.P.Ed. and Lond.

(The Department of Medicine, University of Edinburgh)

AND

D. RIDING, M.D., M.R.C.P. G. E. SHAW, B.Sc., Dip.Bact.

(The Evans Biological Institute)

The treatment of pernicious anaemia by parenteral injections of liver extracts has almost universally replaced the oral administration of whole liver. Among the disadvantages of whole liver are its relatively high cost, the difficulty of ensuring a regular supply, the distaste engendered by its prolonged administration, and the uncertainties attending its assimilation in patients whose digestive and absorptive processes are impaired. Recent reports, however, have indicated the superiority of whole liver in the treatment of certain types of macrocytic anaemia, such as those occurring in pregnancy, sprue, and tropical nutritional deficiency states; occasionally cases of these anaemias have in fact been shown to be refractory to fractionated liver extracts administered parenterally but amenable to whole liver given by mouth. Accordingly it occurred to one of us (D. R.) that it might be an advantage to administer to such patients whole liver in a soluble predigested form.

"Proteolysed Liver"

In the normal physiological process of assimilation of whole liver, absorption presumably begins as soon as any soluble split products are formed as the result of acid peptic digestion and alkaline tryptic digestion. In view of the impossibility of reproducing these processes exactly in the laboratory it was decided to attempt the experimental preparation of predigested whole liver. Papain was chosen as a suitable enzyme for use, since this will react at the natural *p*H of minced liver—namely, approximately *p*H 5.6. In this way the danger of the destruction of active principles by exposure to acid or alkaline conditions would be avoided.

Process of Preparation.—Take 330 lb. of minced liver in a steam-heated pan. Add 36 gallons of water and 660 g. of papain, and heat the mixture to 60° C. Maintain the temperature at this level for three hours. Then raise the temperature to 100° C. and boil vigorously for ten minutes. Strain the hot digestion mixture through cloth, and concentrate the filtrate at a low temperature in a vacuum still to 20 gallons. Clarify the concentrate by filtration, using sterilized kieselguhr as a filter aid, and then sterilize by filtration through suitable asbestos pads. Dry the sterile liquid in a low-temperature vacuum oven.

Properties.—The product thus obtained is a dry, sterile, granular light-brown powder which is not unreasonably hygroscopic. It is completely soluble in hot or cold water, giving a solution that is reasonably palatable, being free from the characteristic liver flavour. It seems probable that as the cell walls are disrupted a high proportion of the water-soluble constituents will be liberated and hence retained in the final product, and that any active principle initially present as a protein complex will be set free and so be rendered available for immediate absorption. In proteolysed liver there is present predigested protein material in addition to essential haemopoietic factors. Fats, fat-soluble vitamins, and coarse indigestible material are alone discarded. It is estimated that one ounce of proteolysed liver powder is derived from approximately six ounces of raw "wet" liver, after allowing for losses due to the mechanical process. A chemical analysis gave the following data:

Loss at 100° C. (moisture)	6.2%	Copper	0.003%
Nitrogen	12.7%	Iron	0.04%
Ash	5.8%	*p*H	4.95

Preliminary tests indicate that riboflavin is present in a concentration of 10 mg. per 100 g., as determined by the method of Shaw (1939).

Thanks to Dr. Bullock of Manchester University, it has been possible to spray dry the sterile liquor, and thereby obtain an even more satisfactory product.

Clinical Trials

The suggestion that proteolysed liver may prove of value in the treatment of certain macrocytic anaemias refractory to the usual liver extracts renders it desirable that the efficacy of this preparation should first be determined in the treatment of the much commoner and more readily available cases of classical Addisonian pernicious anaemia. The object of the remainder of this communication is therefore to record the results obtained in the treatment of five such cases.

All the patients were typical examples of pernicious anaemia in relapse as regards both their clinical and their haematological features. Four of them had received no liver therapy before admission to hospital. The other patient (Case 4) had been treated for pernicious anaemia seven years previously, but had received no treatment during recent years. In all cases examination revealed a macrocytic hyperchromic anaemia with marked anisocytosis and poikilocytosis, and sternal puncture showed a cellular megaloblastic marrow. A histamine-fast achlorhydria was also present in all cases.

As soon as the diagnostic investigations had been completed, treatment with proteolysed liver was instituted. No other haematinic substance was administered during the stay in hospital. The liver preparation is in the form of a granular powder readily soluble in water. For administration it was dissolved in warm but not boiling water, pepper and salt being added to taste, making a beverage which was found by the patients to be quite palatable. The dosage given varied from two to eight teaspoonfuls of the powder daily, equivalent by weight to two drachms and one ounce respectively. The preparation was conveniently given twice daily. Arrangements have been made for the patients to continue taking proteolysed liver in a daily dose of one teaspoonful on their discharge from hospital, and they are being closely observed as out-patients. The present communication is necessarily concerned only with the therapeutic results observed during the period of treatment in hospital.

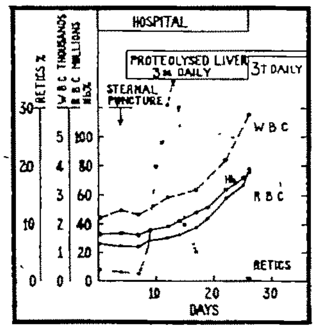
Without exception a satisfactory response was noted within a few days of the institution of treatment. In one case (Case 5) reliable reticulocyte counts were not available, but the progressive improvement in her blood picture left no doubt concerning the effect of treatment. The other four patients all displayed a significant reticulocyte response, which was followed by a progressive amelioration of their clinical and haematological conditions.

The salient features of the cases are displayed for the sake of brevity in the accompanying table, in which are set out the blood counts before treatment and on discharge from hospital, the time and degree of the observed reticulocyte responses, the duration of treatment, and the dosage employed.

Summary of Results of Oral Administration of Proteolysed Liver in 5 Typical Cases of Addisonian Pernicious Anaemia (These data are relevant only to the period of treatment in hospital)

*Blood Counts	Case 1 aged 72	Case 2 aged 50	Case 3 aged 60	Case 4 aged 51	Case 5 aged 44
Hb *a*	23%	32%	35%	44%	50%
,, *b*	61%	75%	75%	80%	83%
R.B.C. (millions):					
a	0·88	1·28	1·37	1·71	1·84
b	2·85	3·88	3·70	3·86	3·54
Rise during first 2 weeks of treatment	1·08	0·92	1·01	0·57	1·11
Colour index:					
a	1·30	1·25	1·28	1·30	1·36
b	1·07	0·97	1·01	1·04	1·17
W.B.C.					
a	—	2,200	2,500	2,200	4,000
b	—	5,800	7,800	4,800	5,400
Reticulocytes:					
Maximum response	35%	35%	17%	22%	—
Time of maximum response	9th day	8th day	7th day	12th day	—
Time of commencement of response	4th day	4th day	4th day	5th day	—
Duration of treatment	34 days	21 days	29 days	20 days	20 days
Dosage daily	℥j	℥ss	ʒij	ʒij	ʒij

* Under this heading "*a*" refers to the count before starting treatment, while "*b*" refers to the final count before discharge from hospital.



Graph showing response to treatment with oral proteolysed liver in a case of pernicious anaemia (Case 2).

The average rise in red cells per c.mm. was 0.94 million during the first two weeks and 1.74 millions during the first three weeks of treatment. As regards dosage, an adequate daily dose appears to be two drachms, but in certain resistant cases it is possible that a larger amount may be desirable. It should be noted that this amount is derived from less than two ounces of raw liver. Since half a pound of raw liver is the usual minimal daily quantity necessary to produce a satisfactory response in pernicious anaemia, it would seem that proteolysed liver is relatively much more effective.

Details of one typical example are given herewith.

Illustrative Case

The patient, a married woman aged 50 (Case 2 of table), gave a history of pallor, increasing breathlessness on exertion, palpitations, nausea, and flatulence of several months' duration. Latterly she had also complained of a sore tongue and tingling of her extremities. Physical examination revealed marked pallor with slight icterus. Nutrition was slightly below standard. The tongue was atrophic. The liver and spleen were slightly enlarged. No enlargement of lymph glands was noted. No evidence of purpura was seen.

Laboratory Examination.—Icteric index, 25; gastric analysis—histamine-fast achlorhydria; Wassermann reaction negative; sternal puncture—cellular megaloblastic marrow with some maturation arrest of the granulocytes. Peripheral blood examination showed a picture typical of pernicious anaemia in the stage of relapse. Further details of blood counts are shown in the accompanying chart.

Treatment.—Proteolysed liver extract was given orally in daily doses of one tablespoonful.

The patient was discharged from hospital 21 days after admission with a great improvement in her physical condition and a gain of 2·6 million red cells per c.mm. She was instructed to continue taking proteolysed liver, one teaspoonful daily.

Discussion

It is not our purpose to advocate the routine use of proteolysed liver in the treatment or maintenance of classical cases of pernicious anaemia. In such cases the existing practice of parenteral injection of reliable liver extracts is economical and effective, and in maintenance treatment has the advantage of assuring that the patient actually receives a known amount of liver extract regularly.

A consideration of obvious importance is that of cost. If it should prove practicable to market proteolysed liver at a price that will enable the cost of treatment with it to compare favourably with existing parenteral therapy, the former preparation would have advantages in the treatment of certain classes of patients—namely, those who may be situated in circumstances rendering regular injections inconvenient, those who object to injections, and those who are allergic to liver extracts injected parenterally.

It is in the field of refractory anaemias, however, that this preparation may find its most valuable application. These anaemias include cases idiopathic in origin, cases associated with pregnancy and the puerperium, and those resulting from nutritional disorders such as sprue. Although a study of the literature may lead to the conclusion that these refractory anaemias are extremely rare in temperate climates, our own experience during recent years has led to a contrary opinion.

Personal observations in support of this suggestion have recently been made on three such cases of refractory megaloblastic anaemia of idiopathic origin, which are responding to oral administration of proteolysed liver. The details of these cases are not now submitted, as it is felt desirable to continue their observation for a longer period and to await the opportunity of studying additional cases.

It is also possible that various factors present in proteolysed liver additional to the liver principle of Castle may render this preparation of value in the treatment of certain anaemias associated with a normoblastic bone marrow.

Summary

A method is described for the production of a palatable and readily assimilable whole-liver preparation by means of enzyme digestion of raw liver with papain.

The name "proteolysed liver" is proposed for the resultant product.

Proteolysed liver administered orally has proved effective in the treatment of five cases of Addisonian pernicious anaemia.

The possible value of proteolysed liver in the treatment of classical pernicious anaemia and of refractory megaloblastic anaemias is discussed.

[*Note.*—It is necessary to state that proteolysed liver is not at present available commercially.]

Our thanks are due to Prof. D. M. Dunlop for allowing us to use two patients under his care for the purpose of this investigation.

THE RELATION OF SUNLIGHT TO DESERT SORES

BY

J. M. HENDERSON, M.D.
Captain, R.A.M.C.

Type of Sore

In the series here described the sores took the form of annular subepithelial whitlows occurring on the exposed surfaces of the limbs, and varying in size from 1 to 3 cm. To lend certainty to the diagnosis of what is undoubtedly a distinct clinical entity, only patients presenting six or more of these lesions were included in the group of 50 cases studied. The cases arrived at an advanced dressing station during July and Aug., 1942. They represent roughly a cross-section of the cases occurring among certain armoured divisional formations during this period. When complications did not arise all were treated as out-patients. Many cases were seen at a very early stage of the disease.

Differential Diagnosis.—The group of sores which are peculiar to desert countries are, in my opinion, those lesions of the exposed surfaces which are commonly seen in the form of subepithelial whitlows, and which are characterized by slowness of healing. Furunculosis is frequently seen in the desert; its differentiation is easy, as the lesions are typical and bear no resemblance to desert sores. Chafing of the feet by ill-fitting boots may give rise to septic sores; these heal rapidly when the cause is removed. Epidermophytosis of the feet may sometimes be complicated by sepsis; a march usually reveals the characteristic erythema and vesiculation of this disease. Insect-bites which have become septic are usually brawny and have a necrotic core. They are not infrequently found on those areas of skin which are exposed only in the sleeping individual—e.g., in the region of the ankles and shin.

Relation of Trauma to Occurrence of Sores

As trauma is an accepted aetiological factor its relation to this series will be described first. It is of considerable interest that 21 out of the 50 patients were unable to account for the presence of the sores. They stated that they did not believe them to be due to injury. In the 29 other cases the majority thought that one or more sores were due to knocks or cuts, but were able to point out a number of sores the presence of which they did not believe to have been caused by trauma. In 6 cases only was the statement made that injury had occurred at the site of every sore.

In cases in which sores are multiple it would therefore seem that a large number appear without history of injury. Bearing this in mind, it is of interest that 19 patients volunteered the information that their sores first appeared as what they described as "water-blisters." Apurulent vesicles were present in only five of these cases when they were first seen by me. Failure to observe vesicles in the majority of instances in which they were described by patients is probably due to the fact that they are present only in the early progressive stages of the disease. In the apurulent stage they vary from 2 to 10 mm. in size. Twelve to twenty-four hours after they are first seen rupture occurs and the sores become purulent in most cases. They become spreading subepithelial whitlows which are resistant to treatment, two to three weeks commonly elapsing before they have healed completely. It is therefore the stage of subepithelial whitlow which is usually seen.

Certain features of the original clear vesicles are of interest. Itch may be experienced in the parent skin for several hours before they appear, but when the vesicles are fully developed they neither itch nor pain. The lack of pain is in marked contrast to the later stages of subepithelial whitlow. When the patient comes for treatment for sores which are fully developed, one or more of these small vesicles may be present of which he is quite unaware. The vesicles were multiple in two of the five cases in which they were observed in this series. I have often seen them on skin which has been reddened by the sun and on the back of the hand, sometimes on skin which was shiny and even atrophic in appearance. Like the later stages in which whitlows have developed, there is no underlying palpable infiltration, nor is oedema of the dermis clinically apparent; marked inflammatory reaction is absent from the surrounding skin. They might thus be described as atrophic in appearance, and closely resemble the vesicles which arise from minute burns or scalds. 0.2 c.cm. of fluid from the vesicle of a colleague was introduced intradermally and aseptically into my own skin at a site corresponding to that of the vesicle of which use was made. No visible reaction occurred in the inoculated area. The vesicular fluid probably does not contain organisms which are markedly pathogenic.

It had to be borne in mind that these vesicles might have been caused by insect-bites. A common origin of this nature is, however, somewhat discounted in so far as they bore no noticeable resemblance to the usual reaction to insect-bite; oedematous papules and petechiae were not seen. Only one case of the series gave a history of having suffered mosquito-bites, and the clothes of the patients were free from lice and fleas. During the greater part of this period of two months the men were in areas in which mosquitoes and sandflies were not prevalent. On the other hand, for one period of three or four days some of these troops were in an area in which they were extensively bitten by mosquitoes, and oedematous papules appeared in large numbers during this short time. None of these papules were observed to develop into the vesicles which have been described, and no noticeable increase occurred in the incidence of desert sores. Insect-bites may occasionally be the cause of this vesiculation; it is unlikely that they are the causal factor in all instances. Similarly, where the vesicles may have resulted from insect-bites it is worth while bearing in mind that the lesion is atypical in the sore-bearing areas, papulation being absent and the lesion taking the form of a vesicle.

In one case which I have seen, though it was not included in the series, the sufferer was a regimental medical officer. Two vesicles were present on the knuckles, and a third had ruptured. He stated that he had definitely knocked the area. As he could be regarded as a reliable witness it is probable that some of these vesicles are the result of knocks that are insufficient to produce either bruising or scarification.

One may conclude that the subepithelial whitlows, or "desert sores," often made their appearance as the result of the skin having been abraded by minor injury. In the case of a large number, however, they first appeared as vesicles, which by their nature indicate intactness of the cuticle. The origin of the vesicles is uncertain. One case of the series had suffered mosquito-bites. A case is noted in which trauma had occurred at the site of the vesicles. In 18 cases, however, the cause was not apparent.

Complications

In this series two patients developed low-grade cellulitis and three adenitis. Lymphangitis was seen in one case of adenitis. There were no cases of diphtheritic palsy. In all five cases in which complications arose they appeared after the sores had been present for some days. They probably signified the contamination of the open sores by relatively virulent organisms.

Coincident Facial Impetigo

In 12 out of the 50 cases impetiginous lesions were present on the face, often in the neighbourhood of the mouth or ears. Thus facial impetigo was observed in one case out of every four. This must be regarded as an unduly high incidence, and leads one to believe that its occurrence is in some way related to the typical subepithelial whitlows of the limbs. In 4 cases impetiginous sores were present on the neck.

The Relation of Season

During the months of March, April, and May, 1942, I saw no cases of the disease, though during the same months a very large number of men were treated at morning sick parade. Cases reporting sick with minor illness were few during June on account of the circumstances of the battle. Case-taking disclosed that only one patient in the series claimed that he suffered from sores all the year round. One man stated that they first appeared in April. In 15 cases the onset occurred during the month of June, and of those claiming onset in July there were 26. Desert sore does not therefore seem to be a disease of the late winter and spring, and cases only begin to appear in numbers in the early summer.

Of those who had not experienced a previous summer in the desert 1 had been in the desert three months, 4 for six months, 24 for eight months, and 1 for eleven months. It is significant that in these cases the sores chiefly made their appearance in either June or July rather than at times related to the duration of their stay in the desert. Only one of the patients spending their first summer in the Western Desert stated that he had previously suffered from desert sore. This turned out to have been in Afghanistan in similar country during 1939.

These cases suggest that the sores mainly appear during the summer. Confirmation of this was sought in the past histories of those patients of the series who had seen two or more desert summers. It was found that out of the 11 patients who had spent one previous summer in the desert 8 had suffered during that summer. The sores had appeared in typical form; they did not recur during the winter months. Of four who had had two previous summers in the desert, all had similar attacks during each of these summers. Only one patient had spent three previous summers in the desert, and he had suffered during all three. Significant statements volunteered by patients were: "They broke out about the same time last year, and the year before that"; and "They appear each year just when the sun gets hot."

In respect of season in the Western Desert, I was able to note the main changes in the weather. During the winter months of December, January, and February the weather is cold, and in 1941-2 cloudy days were numerous. In March, April, and May the cloudy days became less frequent and the weather warmer. By June the days had become relatively cloudless. In July the sun was noticeably hot day after day, and the sunlight relatively intense, giving rise to numerous cases of disturbance of vision. I myself tan deeply, and during July noticed a very marked increase in the laying down of pigment in the skin of my knees and forearms, to an extent greater than I had ever before experienced. The seasonal changes mainly resolve themselves into sunlight and heat factors. It was noticeable that the latter was always greatly modified by the desert wind. This enabled the individual to carry on activities which would otherwise have caused heat-stroke. No cases of heat-stroke were seen.

It would thus appear that, allowing a seasonal incidence of desert sore, the factor most likely to be of importance is sunlight. Bearing this in mind, it was decided to estimate, so far as was possible, the part played by the individual resistance to the sun's rays.

Relation of Orientation of the Individual to Sunlight

Differentiation of individuals resolves itself into two main groups. In the first, marked pigmentation of the skin occurs, and reddening and scaling are absent. In the second, in the extreme case, the exposed skin is unable to adapt itself, and erythematization is the chief reaction to exposure, attended in many instances by dryness of the skin and repeated scaling; the individual often points out that his skin is at this stage abraded by the least knock; he complains that he cannot "take the sun." While many persons fall between these two groups, it seemed from clinical study that it was among the second group that cases of desert sores were most frequently found. As might be expected, the majority of those in the first group also showed the natural evidences of pigment-forming powers; they were most often brown-haired and brown- or grey-eyed. Similarly, lack of pigment-forming power was most common among the fair-haired blue-eyed. The division is not a strict one: a small number of brown-haired, frequently blue-eyed individuals react badly, becoming florid rather than tanning, while a small proportion of the fair-haired develop quite a deep tan.

The percentage of fair-haired individuals occurring among the 50 cases of desert sores was compared with the percentage of fair-haired in a unit the personnel of which were drawn from all parts of Britain. Of the men with desert sores 70% were fair-haired, as opposed to 36% in the control group; and 76% were blue-eyed, as opposed to 28% in the control group. While these figures are drawn from a relatively small number of cases, the disparity is so marked as to indicate that desert sores are much more common among the fair-haired and blue-eyed than among other groups, thus confirming the impression gained by clinical experience. Of the 15 brown-haired individuals who developed the condition 11 were noted to react badly to sunlight.

It may therefore be stated that desert sores tend to occur among those whose pigment formation is below average.

Distribution of Sores

The sores occurred on the surface skin which was exposed. Subepithelial whitlows, however, were seen only on the hands, fingers, arms, and legs. They did not occur on the face and neck, though it has been pointed out that impetiginous lesions were not uncommon in these areas.

Incidence in Susceptible Areas

	Hands	Forearms	Upper Arms	Legs
Incidence in susceptible areas (%)	96	68	4	26
Bilateral (%)	88	32	2	8
Unilateral (%)	8	36	2	18

In the above table sores on the fingers were included under the heading of "hands." As is shown, the hands are most commonly affected. Three factors may be of significance in this respect: (*a*) The hands are most liable to suffer trauma; (*b*) the surface hair is less well developed than on the forearms; (*c*) in the very fair-haired the skin of the back of the hands often becomes red and glazed as a result of frequent and prolonged exposures to sunlight.

In the two cases in which there were sores on the upper arms, sores were also present on the forearms. The sleeves of the shirt were in both cases worn very short, and the effects of exposure to sunlight were as obvious on the upper as on the lower arms. It was characteristic that no sores appeared on the ventral aspects of hands or fingers. They were seen on most of the exposed areas of the forearms. No sores were observed, however, on the area of the skin normally resting against the body in the standing individual. The same part of the skin of the forearm is apposed to the driving wheel, or in the sitting person to the desk or table. Even in deeply tanned individuals it remains free of pigment to a great extent; it appears to be always protected from the sun's rays by posture.

With regard to the knees the sores were more frequently unilateral. The sores occurred here in the areas exposed when wearing shorts and stockings. This area tans uniformly in front and behind. Sores often occurred posteriorly as well as anteriorly.

Four Typical Cases

Case 1.—Trooper A. This case was illustrative of the average mild one. The sores were typical subepithelial whitlows, and were present on the back of the hands and the back of the right wrist. None were present elsewhere. They had first appeared at the beginning of July. Some of the sores he believed to have been due to knocks, but he was unable to account for the presence of others. He states that in the case of one sore, "A big water-blister came up and burst." His hair was fair to ginger and his eyes blue. He volunteered the statement, "My skin sunburns easily"; and again, "If I knock my skin against anything it breaks."

Case 2.—Rifleman B. The sores were very numerous in this case, which was a severe one. Whitlows were present on the back of both hands and on both forearms. One sore was present on the left upper arm, and three on the right upper arm. The sleeves were worn very short. The lower halves of the upper arms were sun-reddened and peeling in the area in which the sores appeared. There were neither sores nor scars on the part of the forearm which rests against the body in the standing individual; they were seen only on the reddened and peeling areas The sores had first appeared at the end of June. The patient believed that the sores were due to knocks in some cases, but not in all. He stated, "I sometimes wake up and look at my hands, and find they are festering." He had spent two previous summers in the desert, and during the second of these had had sores on the knees as well. He believed they had broken out about the same time in each of these summers. He was fair-haired and blue-eyed, reddened rather than tanned, and laid down no pigment in the exposed areas.

Case 3.—Driver C. This case is characteristic of the 19 who volunteered the information that their sores first appeared as "water-blisters." The sores were typical. They were present on the right forefinger, the back of the right hand, and on the right elbow. One was present on the left upper arm, one on the right knee, and one on the left knee. They first appeared at the beginning of July. He had been in the desert for eight months and had had no previous attacks. He was dark-haired and blue-eyed. He was florid in type, and stated, "I keep getting red and peeling."

Case 4.—Sergeant D. This case is of interest in view of the past history. The sores when first seen were very numerous and were present on both hands and knees. They had first appeared in July. This soldier had been in the desert for 40 out of the preceding 48 months. In 1939, when he first came up to the desert, short-sleeved shirts were being issued. During the summer of that year he suffered desert sores on the forearms as well as on the hands. Long-sleeved shirts were issued at the end of the year, and he wore the sleeves down, as he had found that the least knock took off the skin of the forearms, and the site of the knock went septic. He also found that since he had worn his sleeves down desert sores had not occurred on his forearms. He believed that his sores appeared only during the summer months. He was of the opinion that none of the sores were due to injury. They had all come up as clear vesicles, which he described as "sweat-blisters." His hair was fair and he was blue-eyed; he was very susceptible to sunburn.

Discussion

It has been shown that the multiple desert sores of this series appeared only in the areas of the limbs which were exposed to sunlight. In two cases in which sores were present on the upper arms shirt-sleeves were worn very short. One patient had discovered during a previous summer that he was able to avoid sores on the forearms by wearing his sleeves down. The sores were found chiefly in individuals whose powers of adaptation to sunlight were below average. They appeared in almost epidemic fashion at the beginning of the desert summer, of which the main characteristics are increased duration and intensity of sunlight and rise in temperature; the latter factor is modified by the more or less constant desert wind.

It would thus seem that the effects of sunlight play an important part in the aetiology of the sores. It is well known that, in the fair-haired especially, marked changes occur in the exposed skin as a result of repeated and prolonged exposure. The skin becomes erythematous, and frequent scalings take place. Eventually it is found that the least knock takes off the skin. This factor would appear to be of importance in cases in which sores follow slight trauma.

On the other hand, a large group existed in which the individual either was unable to give any history of trauma or believed that the site of only one or two sores had been injured. In spite of this, these cases often showed as many as 10 to 15 sores in the exposed areas, numerous sores being present on the forearms, where minor injuries or "knocks" are not noticeably frequent. Similarly, in a large number of cases the sores were stated to have first appeared as "water-blisters" or vesicles, and in some instances these vesicles were observed. If trauma had given rise to the latter it could only have been minimal, as the fact that the lesions took the form of vesicles precluded rupture of the cuticle. The vesicles were most often found on the areas of skin which were most exposed to sunlight, and in a few cases this skin had become both erythematous and atrophic in appearance. For the reasons which have already been detailed, it is most unlikely that they all followed insect-bites. Only one out of 19 patients stated that he had been bitten by mosquitoes; one other case is described in which the vesicles followed minor trauma. The origin of the vesicles is therefore obscure in a large number of cases. Since many appeared on areas which had been chronically sunburned, it may be that they represent a delayed reaction to excessive sunlight, the vesicles developing either on damaged skin as a result of additional sunburn or from minor and unrecognized trauma, the threshold of the injury having been lowered as a result of the changes in the skin. It is of interest to note that the vesicles resembled small burns or scalds in their clinical characteristics. They were the precursors of many typical desert sores which arose as a result of secondary infection of the vesicles.

The desert soldier tends to suffer excessive exposure to sunlight, and the reasons for this are not obscure. In the forward areas shelter from the sun's rays is lacking. Tents are not pitched by combatant units, as they lessen mobility and are aids to observation from the air; they are also hindrances to effective dispersal. Even the shade provided by vehicles is denied to many by the nature of their duties—e.g., gun crews, Bren-gun carrier personnel, tank and armoured-car commanders, drivers of open trucks. No shade is provided by Nature. Personnel are therefore subjected to repeated and prolonged exposure to sunlight, which in other circumstances they would avoid.

Sand may act as a foreign body and delay healing where contamination occurs, though it should be possible to avoid this if the sores are seen early and are effectively dressed. Flies may be of importance in transferring virulent organisms; in fly-infested regions they may cluster on the sores even while the dressing is being changed. While the possibility of vitamin deficiency cannot be discounted in an appraisal of the aetiology of these sores, the absence of any of the features of scurvy in cases of desert sores would appear to indicate that deficiency of vitamin C is not of major importance. Also, sores have been seen to develop in desert troops who were receiving an apparent sufficiency of fresh food (personal communication of Colonel Ardagh, N.Z.M.F.).

Notes on Preventive Treatment

The following measures have been adopted so far as is possible in cases which I have seen recently:

1. Patients have been instructed to wear their sleeves down. Where the sleeves showed signs of having shrunk the men were told to exchange their shirts for ones with longer sleeves. Protection of the forearm is thus provided against trauma, the effects of sunlight, and insect-bite. If the sleeves are long enough some degree of protection is also afforded to the hands.

2. For the same reasons the susceptible were also advised to wear long trousers.

3. The difficulty of adequately protecting the hands and fingers is apparent. A supply of vanishing cream or of oil, preferably containing a small amount of antiseptic, might be helpful. It would have to be applied to the hands each morning after washing, as washing would destroy the protective film. Only the susceptible of a unit, usually well known to the medical officer by reason of many visits to the M.I. room, would need to be so supplied.

It is of interest to note that some "desert rats" who had experienced previous summers in the desert, and who were susceptible, had obtained a supply of germolene and of elastoplast while on leave. They had found that these were the most useful proprietary medicaments for the occasions on which duties compelled them to spend periods at some distance from the nearest medical officer.

Summary

It has been shown that the desert sores of this series bore a marked relation to exposure to sunlight.

It has been emphasized that changes are observable in the exposed skin of those who are susceptible to sunlight. It was in the exposed areas that the sores appeared, sometimes following trauma; in other cases, however, a history of trauma was not obtainable.

Small clear vesicles, resembling minute burns or scalds, were observed to be the precursors of many of the sores. In one such case these vesicles may have resulted from insect-bites; in another they probably followed minor trauma. In the majority of instances no definite aetiological factor could be elicited; the possibility that sunburn contributed the final trauma cannot be discounted.

It has been observed that, in the desert, various factors contribute towards an abnormal degree of exposure to sunlight.

The annual general meeting of the Society for Relief of Widows and Orphans of Medical Men was held on May 12, with Dr R. A. Young in the chair. By the death of Mr. Warren Low the society has sustained a great loss; he had been president for thirteen years and always took the greatest interest in the society and its work. Dr. R. A. Young was elected president in his place. The annual report for 1942 showed that 56 widows had been granted relief and £4,412 distributed. One of the widows died at the age of 95; she had been in receipt of grants for 46 years and had received from the society nearly £4,000. Relief is granted only to the necessitous widows and orphans of deceased members. Membership is open to any registered medical man who at the time of his election is residing within a twenty-mile radius of Charing Cross. Full particulars and terms of subscription may be obtained from the Secretary, 11, Chandos Street, Cavendish Square, W.1.

LYMPHOGRANULOMA INGUINALE (TROPICAL BUBO)

BY

F. A. R. STAMMERS, Ch.M., F.R.C.S.

Brigadier, A.M.S.; Consulting Surgeon, Western Command

With men of the Services scattered throughout the world it is certain that some tropical diseases will be met with increasingly in the United Kingdom. In times of peace small numbers of cases have always been encountered at seaports, but they are now arriving at inland hospitals; and some of the less-well-known ones will at first puzzle those whose lot it is to treat them.

One of the diseases very common among the natives of West Africa is tropical bubo, or lymphogranuloma inguinale ("L.G." for short), and as it also affects Europeans, though in smaller numbers, it will from time to time appear in hospitals at home. Having recently returned from a continuous service of 20 months in Sierra Leone, during which time my colleagues and I saw well over 300 cases of this disease, including about 30 in Europeans, a brief description of it based on this experience may be of help to those meeting their first few cases.

Aetiology.—It is a virus disease of venereal origin, occurring in the Tropics. It affects both sexes—the men by a primary lesion on some part of the genitalia, followed by enlargement of the glands in the groin; the women by vulvovaginitis, esthiomene, and proctitis, the last-named leading to stricture of the rectum, of which I saw very few cases, and these only while working for three months at Colonial Medical Service hospitals during 1941. Only as the condition affects the male will it be discussed here.

Symptoms

The primary lesion—in the form of one or more very small vesicles, pustules, or ulcers, rather like herpes, usually on the glans and inner surface of the prepuce, but also sometimes on the body of the penis—develops within a few days of intercourse, and unless complicated by superimposed infection is of fleeting duration. It causes little or no discomfort, and the patient scarcely ever presents himself at this stage. A few weeks later—3 to 8 weeks—a gland in one or both groins enlarges, usually at the inner end, though not uncommonly at about the middle, and on two occasions I saw the outer ones involved. By this time the primary herpetiform lesion has usually cleared up, though where the glands have enlarged early several minute scabs may remain as evidence; but, as has already been said, the primary lesion is essentially fleeting, and more often than not is entirely unnoticed by the patient, and therefore denied. This may be because, in the uncircumcised, if the prepuce is long and tight, where washing facilities are restricted owing to water shortage, or when the man has never been taught the wisdom of keeping himself clean, it is not uncommon to get a mild balanitis, so that the man thinks the primary of L.G. the same thing. However, L.G. is not confined to the uncircumcised.

It is therefore almost invariably for the enlargement of the glands that the patient seeks advice, and this rarely less than three weeks, and usually around six weeks, after the risk of infection. At first it may be entirely painless, in which case the patient either reports in order to find out the significance of the swelling, or not at all. Later on, however, pain develops. The condition then progresses through such constant phases that definite stages may be recognized: I have described these in official reports, and I repeat them here since the classification is a useful one upon which to base treatment and prognosis. It was described in 1942 in the *West African Military Medical Journal*, in collaboration with Major W. A. Law, R.A.M.C.

Stages of the Condition

Stage I.—A solitary, elastic, freely movable gland, adherent to neither skin nor deeper structures. Little or no constitutional disturbance. Rarely tender, but physical activity may cause pain.

Stage II.—The solitary gland becomes adherent to the skin and deeper structures, and there is a tendency for surrounding glands to enlarge, becoming fused with the original one. In Europeans it is common for the glands along the external iliac artery to be involved, sometimes forming a large mass above Poupart's ligament, and later spreading up to the common iliac and even aortic glands. In some instances there is a brawny mass in the groin, with *peau d'orange* appearance of the skin. The mass is tender and painful but non-fluctuant, and the constitutional upset considerable: temperature up to 103° F., pulse around 100, malaise, anaemia, bronchitis, jaundice, etc. This constitutional disturbance is always more pronounced in the European than in the native. A section of the original glands at this stage has a very characteristic appearance, looking like a gland packed with tiny abscesses.

Stage III.—The original mass, be it large or small, softens in one or more places, and fluctuates, and the general condition of the patient improves. I have never seen the glands along the external iliac artery break down. On section the softened area consists of a cavity broken up by interlacing trabeculations of fibrous tissue and containing sterile, glairy, sticky fluid that adheres to the knife, the whole process being the result of coalescence of the earlier tiny points of necrosis.

Stage IV.—Spontaneous fistulation has occurred and secondary infection quickly follows.

Comments on Diagnosis

It is, of course, essential to examine thoroughly for any other source of infection. Ulcers are so common on the legs of natives that doubt may arise as to the true nature of the glands. In the same way abrasions on the skin, chafing by the boot, athlete's foot, etc., may be a source in the white man. The Frei intradermal test will here be of great help, and gives a reliable result in 90% of cases. Small lesions in the urethra have been described, but none was seen in a series that we urethroscoped. General congestion of the urethra, on the other hand, was common.

In brief, it may be said that a mass confined to one or both groins, conforming to any of the four stages described, in the absence of any other possible source of infection and with a positive Frei test, spells lymphogranuloma inguinale. The condition most likely to be confused with it in Europeans is tuberculous glands, and we made this error in our first European case. However, the Frei test was not then available, but is the differentiating point.

Treatment

There is no doubt that among natives a number of cases never pass beyond Stage I, and subside spontaneously without the men ever reporting sick. It is an observed fact, too, that in some of those reporting in Stage I and put to rest in their billet for a few days the condition subsides spontaneously. But the difficult case is the Stage II one that in spite of rest shows no improvement but rather a worsening. It is to such cases that this communication especially draws attention, since the European behaves in this manner—hardly ever clearing up spontaneously, even in the rare event of not progressing beyond Stage I; the vast majority pass well into Stage II with marked constitutional effects. The various lines of treatment available are as follows:

1 Rest in Bed.—Local applications of heat to the glands by fomentation, antiphlogistine, or radiant heat and infra-red lamp.

2. Intramuscular injections of anthiomaline (10 to 20 injections), an antimony preparation, as described by Major W. A. Law in the paper already quoted.

3. Intravenous injections of sodium antimony tartrate.

4. Large Doses of Sulphonamide.—We began with sulphapyridine, giving as much as 96 g., spaced over 3 to 4 weeks, in three courses. Careful watch on the white cell count must be kept. Later on, because of the higher price of sulphapyridine, we ran a series on sulphanilamide, using about the same amount, at roughly one-third of the cost. Later on still, we treated some natives with intramuscular injections of a suspension of sulphapyridine in water. This requires about one-quarter of the above amounts, and was seemingly just as successful. The method was a natural sequel to the highly successful treatment of gonorrhoea in this way by Capt. England and others on the West Coast. Care has to be taken not to inject the drug near a large nerve root, as cases of permanent interstitial neuritis have been reported, though no accident occurred at a general hospital where this work was carried out. In order to avoid the risk of such a catastrophe the vastus externus muscle is the site of election.

5 Injections of triple typhoid vaccine (T.A.B.) 50 millions intravenously—about six injections at three-day intervals.

6. Surgical Excision.—We tried a small group of cases by this method. Those in Stage I do well, healing by first intention and requiring about ten days' hospitalization followed by a week's convalescence. Early Stage II cases can be treated by excision too, but the wound is liable to become moist, and in the brawny stage surgical intervention is contraindicated, the wound always breaking down.

Comments on Treatment

The untreated Stage II case will never resolve spontaneously—it tends to linger in Stage II for weeks and then the mass breaks down. Treatment by local heat hastens this breaking-down process but rarely encourages resolution. The various drug methods, on the other hand, cause a large proportion to resolve—often quite quickly; but even where this does not occur the mass breaks down quickly, and so in either event a prolonged Stage II is avoided. The majority of cases treated with anthiomaline, sodium antimony tartrate, sulphonamides, or T.A.B. are cured, apart from a little residual thickening in the groin, and fit to return to their units in 3 to 4 weeks; anthiomaline is perhaps the best by a few days, but it is expensive. Its chief advantage is that, where constitutional reaction is not great, it can be given to the man in his unit M.I. room, whereas the others require bed treatment. However, as most Europeans do get a marked constitutional disturbance, the point is not so important.

Stage III has been treated in many ways, and there is a natural temptation to incise the fluctuating swelling. This, however, is the worst possible treatment, for experience shows that secondary infection rapidly develops and the wound continues to discharge for weeks. All are agreed that under no circumstances should incision ever be practised. The best treatment is aspiration, which may have to be at several points because of the tendency to loculation, and it may have to be repeated once or twice. It must be carried out with aseptic precautions, and the punctures should be covered with a patch of sterile gauze and elastoplast. Another method is to use a seton, and a piece of silkworm-gut transfixing the cavity serves well, though the device is not so satisfactory as aspiration.

The treatment of Stage IV is really the treatment of the secondary infection; a combination of dry heat and sulphonamides, with rest in bed, is necessary, and is eventually effective.

Recurrence.—A small proportion of our 300 cases showed recurrence of the glandular swelling, but this soon subsided under the influence of a second, shorter, course of the original treatment.

I should like to acknowledge the work of the various officers who successively took charge of the V.D. Department, and to express thanks to Colonel L. A. Harwood, T.D., the commanding officer of this unit, for permission to publish these cases.

ARSENICAL ENCEPHALOPATHY

A COMPLICATION OCCURRING DURING THE TREATMENT OF SYPHILIS

BY

R. B. NELSON, M.B., D.P.H.

C. McGIBBON, M.B., Ch.B.

AND

F. GLYN-HUGHES, M.D.

The results obtained from the adequate treatment of syphilis with arsenical compounds are among the most gratifying in medicine. Most of the lesions disappear rapidly, and in the primary and secondary stages the Wassermann reaction is quickly reversed to normal, while subsequent treatment in these stages invariably results in a complete cure. The treatment, however, is not without the risks attendant on the administration of a powerful drug, and the toxic effects of arsenical therapy are many and varied. Fortunately the vast majority are mild, and the more severe types, such as deep jaundice and exfoliative dermatitis, are relatively uncommon. But it is to one of the rarest and most fatal complications, haemorrhagic encephalopathy, that we wish to draw attention.

During the past 18 months we have had opportunity of witnessing four cases which we consider typical of this condition. These patients were admitted to the wards after treatment as out-patients at the local clinics, and they are the first cases recorded during the nine years' existence of the wards.

Case I

A man aged 50 first attended the out-patient department on Nov. 21, 1940, with lymphopathia venerea. A positive test to Frei antigen was obtained. A Wassermann test was made as a routine measure; the result was doubtful. Four days later the test was repeated, and a strongly positive reaction was obtained. The patient gave a vague history of a penile ulcer in 1910. On Nov. 28, 1940, he began a course of mapharside and bismuth consisting of alternating bi-weekly doses of 0.04 g. and 0.06 g. of mapharside, and bismuth 0.2 g. bi-weekly. Five injections were given, and on the day following the last he was admitted to hospital in deepening coma. The pupils were small and equal, but responded to light. His knee- and ankle-jerks were present and equal, and the plantar response was flexor. His respirations were stertorous and he was doubly incontinent. There was no paralysis of the limbs, and the attitude of the hands and feet was at times strongly suggestive of tetany. Lumbar puncture showed that the fluid was under slight pressure. Fifteen c.cm. was removed, and 1 c.cm. of adrenaline was given four-hourly Subsequent examination showed the cerebrospinal fluid to be normal. The temperature, which was 100.4° F. on admission, rose within a few hours to 104.2° F., and the man died.

At necropsy the brain was extremely congested on the surface. The cut surface showed very marked congestion of the small blood vessels in the white matter of both hemispheres. Microscopical examination revealed minute haemorrhages surrounding the small vessels. The only other positive finding was a pronounced fatty change in the liver.

Case II

A woman aged 22 attended the clinic with a gummatous ulceration of the hard and soft palates and ulceration of the left tonsil. Her father had a history of syphilis, and she was considered to be a case of congenital tertiary syphilis. She was 27 weeks pregnant. Her Wassermann reaction was strongly positive. Treatment began on March 10, 1942, with N.A.B. 0.3 g. and Bi 0.2 g. The patient returned on March 17 and was given N.A.B. 0.45 g. and Bi 0 2. On March 19 she complained of some headache and dizziness. She relapsed into coma and was admitted to hospital with athetoid movements of the left hand. On lumbar puncture the cerebrospinal fluid was under slight pressure. About 10 to 15 c.cm. was removed, and adrenaline 1 c.cm. was given. A slight increase in protein was found in the fluid. In a few hours the temperature had risen to 109° F., and the patient died.

Examination of the brain showed haemorrhages arranged in a symmetrical fashion in the medulla, both hemispheres, and the corpus callosum. The haemorrhages were punctiform and grouped together, occasionally coalescing to form a larger haemorrhage. They were particularly numerous in the white matter surrounding the basal ganglia, but were also present in the basal ganglia themselves.

Case III

A 24-year-old multipara was admitted to hospital on Jan. 29, 1941 It was her third pregnancy, the previous two having been stillbirths. She showed no clinical signs of either acquired or congenital syphilis The Wassermann reaction and the Meinicke test were both strongly positive. She was then 32 weeks pregnant.

Treatment was given as follows. Jan. 30: N.A.B. 0.15 g., chlorostab 0.16 g. Feb. 3: N.A.B. 0.3 g. Feb. 6: N.A.B. 0.3 g., chlorostab 0.16 g.

Subsequent Course of Events.—Feb. 7: Patient complained of headache and nausea, vomiting once or twice. Feb. 8: The vomiting restarted and increased in severity. Eventually she became irrational and delirious. On examination there was no evidence of oedema or of renal tenderness. Her blood pressure was 155/90. A catheter specimen of urine showed no albumin, but sugar a trace and acetone ++. On auscultation the foetal heart was heard. A provisional diagnosis of toxaemia of pregnancy was made. An intravenous saline drip was set up and morphine given. Feb. 9: The patient was now comatose. There was spasticity of the arms, pupils were unequal, and the right plantar reflex gave an extensor response. Nothing abnormal was observed in the fundi. A lumbar puncture was done for diagnostic purposes. The cerebrospinal fluid was clear and not under pressure. There was no blood present. Treatment was given to reduce the cerebral oedema—viz., 50 c.cm of 50% glucose intravenously and a solution of mag. sulph. 50% P.R. In the evening of Feb. 9 the patient died, the temperature rising to 104.4° F. before death.

Post-mortem Report.—Brain : There were punctate haemorrhages in the centrum ovale and in the roofs of the lateral ventricles. Microscopical examination showed multiple haemorrhages into the white matter. These usually had an obvious perivascular distribution

Both "ring" and "ball" haemorrhages were present. Perivascular demyelination as described by Russell (1937) was particularly looked for, but no evidence was found with either the Marchi or the Loyez modification of the Weigert-Pal method *Liver:* Microscopical examination showed marked cloudy swellings with occasional subcapsular haemorrhages. *Spleen:* Enlarged and soft; subcapsular haemorrhages and petechiae on the cut surface. *Kidneys:* Right showed subcapsular haemorrhages. The cortex was pale, with engorged vessels and glomeruli. The left kidney showed similar changes but no subcapsular haemorrhages. The *suprarenals* appeared normal.

The foetus was examined, particularly the liver. No *Spirochaeta pallida* were demonstrated, nor was there any evidence of syphilitic cirrhosis.

Case IV

A primigravida aged 18 was admitted to hospital on Oct. 29, 1941. She was then 20 weeks pregnant. On examination she was found to have a primary sore of the vulva (*Sp. pallida* +). The Wassermann reaction and Meinicke test were both weakly positive. Treatment was given as follows: Oct. 30: N.A.B. 0.15 g., chlorostab 0.16 g. Nov. 4: N.A.B. 0.3 g. Nov. 7: N.A.B. 0.3 g., chlorostab 0.16 g.

Subsequent Course of Events.—On the evening of Nov. 9 she complained of slight headache, and retired early to bed. The following morning she was stated to have had a fit. When seen a few hours later she was stuporous. There was no neck rigidity; the pupils were equal and reacted to light. Both plantar reflexes gave a flexor response. Heart and lungs were clear. Her blood pressure was then 150/90. A catheter specimen of urine contained a trace of albumin only. The blood urea was 42 mg. per 100 c.cm.

A diagnosis of haemorrhagic encephalitis was made Treatment consisted of repeated drainage of the theca. The first lumbar puncture was done within five hours of the fit.

C S.F. Laboratory Data

	10/11/41	11/11/41	12/11/41	14/11/41	21/11/41
Amount withdrawn	45 c.cm.	30 c.cm.	20 c.cm.	10 c.cm.	5 c.cm.
Appearance ..	Clear	Clear	Clear	Clear	Clear
Fibrin clot . .	None	None	None	None	None
Total protein ..	0·09%	0·12%	0·14%	0·09%	0·04%
Globulin . .	Increased	Sl. inc.	Sl. inc.	Sl. inc.	Normal
Sugar	Normal	Normal	Normal	Normal	Normal
Chlorides .. .	Normal	Normal	680 mg.	650 mg	Normal
Lange .	Negative	Negative	Negative	Negative	Negative
Cells (lymphocytes)	2 per c.mm	2 per c.mm	2 per c.mm.	2 per c mm.	2 per c mm.
W.R. ..	Neg. in all dilutions				Neg. in all dilutions

In addition to drainage of the theca by lumbar puncture 10 c.cm. of mag. sulph. 20% was given intravenously twice during Nov. 10, and thereafter hypertonic mag. sulph. P.R. The patient was kept under the influence of morphine. On Nov. 11 a morbilliform rash appeared on the neck, breasts, and shoulders. This rash disappeared within 24 hours. The maximum temperature was 101.2° F. on Nov. 12; on Nov. 13 and thereafter it was normal. Gradually the patient improved, and two days after the onset of the condition was fully conscious and alert. For a further four to five days she remained irritable and restless. Finally she became her usual self in behaviour and intelligence. A blood Wassermann reaction and Meinicke test done on Nov. 25 were both negative. Antispecific treatment with bismuth was started on Nov. 28, and thereafter was continued at the out-patient department.

On March 11, 1942, she was delivered spontaneously of an apparently healthy full-time male infant, whose weight at birth was 6 lb. 13 oz. The Wassermann reaction of the cord blood was negative and no *Sp. pallida* were demonstrated in the umbilical cord. On April 24 a blood test was done on the child, the Wassermann reaction and the Meinicke test being negative. Radiographs of the long bones revealed nothing abnormal.

Discussion

The so-called haemorrhagic encephalitis is the most fatal of all complications resulting from arsenotherapy. Fortunately it appears to be very rare. Stokes (1934, 1939) observed one case in 63,000 injections. Glaser, Imerman, and Imerman (1935) in a review of the subject found one death due to cerebral complications in every 5,398 cases treated and in every 28,768 injections. Paley and Pleshette (1939) reported one fatality from haemorrhagic encephalitis among 1,200 treated cases of pre-partum syphilis. It is stated that males are slightly more often affected; but of females reported over 70% were pregnant. They were apparently healthy adults, the average age being 22.5 years. The ante-natal cases were usually primigravidae, and the average duration of pregnancy was 5.5 months. In our series of cases the ages were 50, 22, 24, and 18 years. All three females were pregnant. The periods of gestation were 27 weeks, 32 weeks, and 20 weeks respectively. From our own limited experience we suspect that the condition is not so rare as the figures quoted suggest. It is conceivable that such cases might be admitted to medical and ante-natal wards, where, in ignorance of recent antispecific treatment having been given, the diagnosis is not made.

The mortality rate is high. Most cases terminate fatally, although recovery has been reported in several instances by David Lees (1940), Netherton (1934), Dickens (1928), and Parnell and Dudley (1920).

Pathology

The pathological changes are most pronounced in the white matter of the brain, although similar lesions are found to a less extent in the grey substance. It is stated that the sites most frequently involved are the corpus callosum, the caudate and lenticular nuclei, the pons, and the medulla. Globus and Ginsburg (1933) in their description of two cases following arsphenamine therapy indicated that the main central lesions were "ring" haemorrhages. The haemorrhages were pericapillary, and there was no evidence of inflammation. These authors suggested, therefore, that the term "pericapillary encephalorrhagia" was more appropriate than "haemorrhagic encephalitis." In addition to these characteristic haemorrhages reactive gliosis was present in the neighbourhood of the affected blood vessels.

In our post-mortem reports these pathological findings have been confirmed. Pathologists agree, however, that such lesions as described are not peculiar to arsenical encephalorrhagia. They have been observed in association with many diseases.

Treatment

Since the majority of cases are rapidly fatal and are recognized only at necropsy, there is in the literature a paucity of information regarding the relative merits of suggested modes of treatment. In the one case of our series which did recover, repeated drainage of the theca was efficacious. This was instituted 5 hours after the occurrence of the initial convulsion and therefore, one may conclude, before the onset of any appreciable brain haemorrhage or necrosis. In addition this patient was kept under the influence of morphine. Other writers have suggested such procedures as venesection, the giving of large doses of adrenaline intramuscularly, repeated intravenous injections of sodium thiosulphate, calcium preparations, snake venom, and continuous inhalations of oxygen with intravenous injections of urotropin and caffeine.

Theories

The theories as to the cause of haemorrhagic encephalitis are numerous and, examined individually, are not altogether conclusive. As regards the toxicity of the drug administered, no trivalent arsenical is free from the risk of producing this condition. Sulpharsphenamine is stated to be associated with a higher incidence than the other members of the group. N.A.B. and mapharside, the drugs used in the cases reported, are considered to be less toxic than many, and, moreover, the N.A.B. was dissolved in 10 c.cm. of 10% sodium thiosulphate.

The dosage does not seem to play a prominent part in the aetiology, since the largest dose of N.A.B. given was 0.45 g. and of mapharside 0.06 g. Of the other causative factors cited by previous observers, none of our cases showed evidence of chronic arterial disease nor of liver or adrenal insufficiency.

It is reasonable to suppose that pregnancy must have some bearing on the aetiology, since, as already quoted, of women with haemorrhagic encephalitis 70% were pregnant. In one of our cases toxaemia of pregnancy was considered as a provisional diagnosis, and it is possible that an additional toxaemia due to pregnancy may be a predisposing factor. On the other hand, in our own experience a large number of women with ante-partum syphilis, many of them with marked general debility, have been treated with trivalent arsenicals without developing haemorrhagic encephalitis. Furthermore, during treatment a small proportion have presented definite signs of toxaemia of pregnancy. These did not become cases of haemorrhagic encephalitis.

Our post-mortem findings would appear to support the theory of direct toxic action on the brain capillaries. The reason for this apparent selection is obscure, and our observations throw no new light on this aspect. From the study of the four cases reported one interesting feature emerges—namely, the interval between the first injection and the onset of the condition. It is not without significance that in three of them haemorrhagic encephalitis occurred about the tenth day after beginning treatment—a time when it is not uncommon to find other signs of intolerance to arsenic in the syphilitic patient. Indeed, one of our patients did manifest a concomitant morbilliform rash. Haemorrhagic encephalitis does occur in patients receiving arsenical therapy for non-syphilitic nervous disorders, but not with the same characteristic time interval. Therefore one may assume the syphilitic infection itself cannot be excluded as a factor in the aetiology.

Finally, two extraneous factors may be mentioned. It will be noted that these four cases occurred in winter-time, when as a general rule vitamin intake is at its lowest, especially vitamin C. Also they have been reported since the onset of the war. Conditions in wartime naturally impose greater mental stress and strain on the individual, and more so on the patient with syphilis.

Conclusion

Haemorrhagic encephalitis is a rare complication of treatment with arsenic in syphilis.

It is impossible to determine in advance the type of individual who will develop this complication, but the pregnant woman with syphilis should be regarded as a "potential reactor."

The clinical signs are those of cerebral irritation, and may be preceded by such symptoms as headache and dizziness.

The condition is rapidly fatal unless diagnosis is prompt and treatment immediate.

We wish to thank Dr. Ross and Dr. Sanderson for kindly allowing us access to their case.

A CASE OF HAEMORRHAGIC ENCEPHALOPATHY FOLLOWING ARSENICAL THERAPY

BY

JAMES P. A. HALCROW, M.B., M.R.C.P.Ed., D.P.H.
Medical Registrar, E.M.S.

The following case of arsenical encephalopathy is thought worthy of publication in view of the few references to this complication of arsenical therapy in recent British literature, and also because of the increasing incidence of syphilis at the present time.

Cases in the Literature

Serious cerebral complications following treatment with arsenical preparations are fortunately rare. Haemorrhagic encephalopathy or serous apoplexy is a complication of arsenical therapy which usually ensues within two or three days of the second or third injection of an arsenical preparation. The onset is characterized by drowsiness, irritability, and depression, followed by epileptiform convulsions and coma. The prognosis is bad unless cases are recognized early and prompt treatment is instituted. Lees (1937) mentions nine cases, five of which recovered. Winter (1940) describes a case of primary syphilis in a healthy young adult in which symptoms developed two days after the second injection of an arsenical preparation. The early symptoms in Winter's case were slight nausea, headache, and feverishness. Examination revealed a scarlatiniform rash on the trunk, limbs, palms of the hands, and soles of the feet. The temperature rose to 104° F., the rash became more marked, and oedema of hands and arms developed. Vomiting was a feature, but mental and nervous symptoms were lacking. The rash became purpuric, and about 48 hours from the onset mild mental symptoms developed, followed by loss of consciousness and death. Necropsy revealed oedema of the brain and multiple haemorrhages throughout the brain substance. Friedman and Newman (1941) describe a case of encephalitis in a syphilitic subject aged 28; again the symptoms appeared shortly after a second dose of an arsenical preparation. These symptoms were epileptiform convulsions, projectile vomiting, and rectal and urinary incontinence. Examination revealed no abnormal neurological findings. The cerebrospinal fluid was not under pressure; it contained 15 cells per c.mm. and total protein 70 mg. per 100 c.cm. Their case recovered, after administration of adrenaline intramuscularly and glucose intravenously. Friedman and Shinefeld (1941) describe two cases in syphilitic children, both of whom died. In their cases symptoms occurred after several injections of arsenical preparations. The symptoms were irritability, convulsions, and coma. In one case cerebrospinal-fluid protein was 297 mg. per 100 c.cm. Russell (1937) describes the pathological findings in three cases. She found perivascular and ring haemorrhages, and also perivascular non-haemorrhagic areas of necrosis and demyelination in the central nervous system. All three were serologically positive cases of syphilis in young adults, the eldest being 31 years old. Symptoms in two of her cases appeared shortly after the second injection of an arsenical preparation; in the third case symptoms followed the third injection. All three patients died within four days of onset.

Case Report

Male aged 22. No previous history of ill-health. Treated for acute gonococcal infection from March 4 to 12, 1942, in V.D hospital, and readmitted to the hospital on April 12 with multiple indurated ulcers on coronal sulcus. *Spirochaeta pallida* present on examination with dark-ground illumination. Treatment consisted of: April 11: novostab 0.45 g., chlorostab 1 c cm. April 14: neokharsivan 0.3 g. April 18: novostab 0.45 g., chlorostab 1 c.cm. On April 21 the patient felt out of sorts, hot, and flushed; temperature 102° F. During the next two days temperature varied from 100° to 102° F. He was depressed, but made no special complaint At 7 a.m. on April 23 he had an epileptiform convulsion and vomited bile-stained fluid; admitted to E.M.S. hospital.

Examination.—Temperature 98° F., pulse rate 78, respirations 20 Semi-comatose on admission; incontinent, with noisy moaning respirations; colour good. Pupils equal, circular, and contracted: reacted sluggishly to light. No neck rigidity, and Kernig's sign negative. All reflexes were exaggerated and ankle clonus was present; plantar responses doubtful flexor; abdominal reflexes present and normal. Other systems normal. Blood pressure 120/70. *Fundi:* Slight blurring of disk edges right side. Left side normal. *Urine:* S.G. 1030; no abnormal constituents; no red blood cells or casts. White cell count 12,000. Lumbar puncture at 11 a.m: cerebrospinal fluid not under pressure; fluid contaminated with blood. *Blood:* Wassermann reaction ++, Kahn negative Flocculation test, 1:16.

A few hours after admission plantar reflexes became extensor and respirations stertorous. By evening temperature had risen to 104° F. Pulse rate 118; respirations 40. Lumbar puncture repeated: cerebrospinal fluid clear; pressure 250 mm. water; cells 5 per c.mm.; Wassermann reaction negative; protein 230 mg. per 100 c.cm. By the following morning coma was deep, with marked venous congestion. Venesection performed and 14 oz. of blood withdrawn. Lumbar puncture repeated—10 c.cm. cerebrospinal fluid removed: pressure 260 mm. water; cells 5 per c.mm.; protein 270 mg. Kahn negative. By 2 p.m. on April 24 coma had deepened; temperature 104.8° F., pulse rate 108, respirations 32 Marked cyanosis, and at 6 p.m patient had two epileptiform convulsions. Lumbar puncture repeated. Thereafter coma steadily deepened, and after two further epileptiform convulsions the patient died at 3 a.m. on April 25.

Necropsy

Apart from the central nervous system, all organs were normal except for punctate haemorrhages on the upper surface of lower lobe of right lung.

Brain · Macroscopic Appearance.—Considerable congestion of the pia-arachnoid all over the brain, with several irregular haemorrhages—one on the upper surface of the left half of the cerebellum, one on the contiguous lower surface of the corresponding occipital lobe, and a third at the right temporo-sphenoidal lobe. Small cerebellar cone round the brain-stem. Section of brain revealed congestion of grey matter and small congested vessels in the white matter. After fixation, sections of brain revealed a fair number of petechial haemorrhages, more marked in the white matter. Macroscopically the grey matter of the brain was congested, giving a pinkish hue. Many small congested vessels in white matter.

Microscopical Examination.—The lesions present were not numerous, therefore careful searching was necessary. Some blocks of brain tissue did not reveal any lesion. No particular part of the brain was especially involved, the lesions being irregularly distributed throughout the brain substance. They were perhaps more obvious at the junction of white and grey matter than anywhere else in the cortex. Main lesions in intracerebral vessels, consisting of endothelial swelling associated with ante-mortem thrombi, partially occluding the lumen of the vessels. Some of the thrombi were infiltrated with polymorphonuclear leucocytes, many of them eosinophils Occasionally there was evidence of vascular rupture, with red blood cells and eosinophilic material in the Virchow-Robin spaces. No obvious change in nerve cells themselves, and there was absence of perivascular cuffing and other signs of encephalitis. Emulsions of the brain were injected into rabbits and mice with negative results.

Treatment

This consisted of repeated lumbar punctures. Adrenaline was given in doses of 1 c.cm. intramuscularly four-hourly, and sodium thiosulphate was injected intravenously. Venesection was also done. Treatment to be successful must be started as soon as possible, and therefore it is of great importance that this complication of arsenical therapy be quickly recognized. In every case of sudden cerebral disaster in a young adult the question of previous arsenical treatment should be considered.

Discussion

This picture conforms to the usual type previously described in the literature—severe cerebral symptoms, with coma and epileptiform convulsions. The onset generally occurs after the second or third injection of an arsenobenzene preparation, and can happen as readily in the healthy subject as in the unfit. The main features in the present case are the haemorrhages, and extreme congestion of vessels of white matter coupled with blocking of cerebral capillaries and occasional rupture. There was no evidence of non-haemorrhagic perivascular areas of necrosis and demyelination as observed by Russell in her cases. This may have been due to the fact that this patient did not survive long enough for these findings to develop. Two of Russell's cases in which these changes were present survived for four days after onset of acute symptoms. The third of her patients died within six hours; evidence of necrosis and demyelination in the central nervous system was scanty.

The causal factor in arsenical encephalopathy is unknown, and seems to be unrelated to the arsenic radical, as poisoning by arsenic in an inorganic form does not give rise to such cerebral symptoms. It also seems unlikely that overdosage is at fault, as in most recorded cases symptoms have arisen shortly after the second or third injection. It is apparently not of the nature of a Herxheimer reaction, because cases are recorded (Glaser, Imerman, and Imerman, 1935) in which cerebral complications followed arsenical therapy in non-syphilitic subjects.

As symptoms occur most frequently after the second or third injection of an arsenical preparation it seems possible that the cerebral phenomena may be in the nature of an allergic reaction, although this does not seem to be of a permanent nature, as Lees mentions a case in which treatment with an arsenobenzene compound administered intramuscularly was resumed after recovery from haemorrhagic encephalitis without ill effects. There appears to be some relation between purpuric eruptions due to arsenobenzene preparations and haemorrhagic encephalitis (Winter, 1940). It may be that both are due to a toxic action of the benzene radical on capillaries. Organic arsenicals are well known as a cause of thrombocytopenic purpura, and it is possible that in some cases of haemorrhagic encephalopathy the toxic action is due to disintegration of arsenobenzene compounds in the blood, with resulting thrombocytopenia and capillary damage. The case described by Winter in which purpura was a feature could fit in with such a theory. I have been unable to find any reference in the literature to the platelet count in arsenical encephalitis.

The raised cerebrospinal-fluid protein in this case, with a normal cell content, is unusual, as was the increase in the C.S.F. pressure. In most cases described the protein has been normal and the pressure also normal. In the present case, as in others described, the Wassermann reaction was positive in the blood but negative in the C.S.F.

In most cases previously recorded, cerebral complications of arsenobenzene therapy are referred to as haemorrhagic encephalitis. In view of the clinical picture and pathological findings, encephalopathy seems a more fitting description to apply to this complication.

Summary

A case of arsenical encephalopathy with pathological findings is described.

Attention is drawn to the need for early recognition of this condition, as treatment seems unavailing unless instituted in the first few hours after onset.

A short review of the literature is given. No adequate aetiology has been found to account for cerebral complications following arsenobenzene therapy.

I wish to thank Lieut.-Col. G. L. Montgomery, R.A.M.C., Assistant Director of Pathology, Scottish Command, for the post-mortem findings in this case, and Dr. A. A. F. Peel for advice and criticism; also the Department of Health for Scotland for permission to publish this report.

ETHYL CHLORIDE ANALGESIA

BY

J. D. ROCHFORD, M.B., D.A.
Captain, R.A.M.C.

AND

B. T. BROADBENT, L.D.S.
Captain, A.D. Corps

(From a General Hospital in the M.E.)

The term "analgesia" implies the loss of pain sense without the loss of consciousness or the sense of touch (Guedel, 1937). It is generally accepted that during induction of anaesthesia by inhalation a phase of analgesia is passed through (Guedel, 1937). This phase starts at the beginning of induction with a relative blunting of the sense of pain (relative analgesia), and passes to a complete state of analgesia (total analgesia). The analgesic phase ends with the loss of consciousness of the patient, some drugs giving a longer and better analgesic period than others. These drugs have been used for a variety of purposes: chloroform analgesia in obstetrics; trichlorethylene analgesia for the relief of pain in tic douloureux (Striker *et al.*, 1935) and more recently for painful dressings; nitrous oxide in combination with air or oxygen in midwifery and dental work (Minnitt, 1934).

The limitation of the method is the difficulty of maintaining the analgesic state without slipping into the second and most dangerous stage of anaesthesia with its attendant risk of ventricular fibrillation. Lincoln (1941) has made an advance in the production of analgesia by using ethyl chloride in combination with nitrous oxide by the nasal route. It was considered that it might be of advantage to investigate the effects of ethyl chloride alone without using nitrous oxide. This we have done with success in 90 cases, the majority being dental extractions. All these patients were soldiers, many of whom are anaesthetic-resistant subjects.

The Method

The apparatus required is two tubes of ethyl chloride, a dental prop, some vaseline, and a roll of gauze. The lips are smeared with vaseline and a dental prop is inserted. An oblong of gauze, about 2 in. by 6 in., is crumpled and placed between the teeth, but not so far back as to cause gagging. The patient is asked to breathe to-and-fro through his mouth alone. He is told that the vapour will not put him to sleep but will prevent pain. Ethyl chloride is then sprayed on to the gauze on and off for 45 seconds. The amounts we have used vary between 4 and 9 c.cm., the average being about 6 c.cm. If the eyelids are seen to flicker the patient is ready; otherwise it is better to rely on the time period entirely. The gauze is pushed aside and the operation completed. The gauze is then removed and the patient asked to take one or two deep breaths; by the time he has rinsed his mouth out he is ready to leave the chair.

Of the 90 cases 70 were dental extractions and 20 were minor operative procedures, mainly incisions of abscesses. In all cases analgesia was achieved; there were no post-operative complications. The dental cases were not confined to single extractions of upper and lower incisors, as 33% were molars or pre-molars. In several cases a number of teeth were removed, in one case seven. The majority of cases were those in which local anaesthesia was contraindicated. Many of the cases were those in which the patient was a difficult subject, being uncooperative and fearful, as this was his first visit to a dental surgery.

Comment

The advantages of ethyl chloride are many. It is a safe and rapid agent (Hewer, 1930) requiring no apparatus. The method is simple to learn and easy to apply. By Lincoln's (1941) technique of oral breathing induction is pleasant; there is the psychological benefit of having no mask, and there is no struggling—not even by the anaesthetic-resistant patient.

Total analgesia lasts from 60 to 120 seconds; recovery is as rapid as with nitrous oxide. There are no after-effects: we have had none, and in a series of 2,200 cases only 6 complained of nausea (Lincoln, 1941).

It would seem that ethyl chloride analgesia might be useful, particularly in wartime, in the painless extraction of teeth and for such simple operative procedures as opening superficial abscesses. It is cheap, safe, and portable, with rapid induction and rapid recovery.

Summary of Conclusions

Ethyl chloride alone by oral breathing will produce analgesia—that is, a loss of sense of pain with the retention of consciousness.

The method is simple, safe, and rapid, and can for short procedures compare in every respect with nitrous oxide analgesia.

We wish to thank Dr C. Langton Hewer, without whose assistance this article would not have been published; and Lieut.-Col. Ashley Daly, Adviser in Anaesthetics to the Army, for permission to publish it.

Medical Memoranda

Post-scarlatinal Thrombophlebitis Migrans

Thrombophlebitis following scarlet fever is a rare event. The last reported case appears to be that of Rolleston and Ronaldson (1940). Previously Huenekens and Siperstein had recorded a case in 1923. These authors give a full review of the literature, in which they could find only 9 cases reported since 1882.

CASE HISTORY

A boy aged 11 was admitted to the East Malling Isolation Hospital on Feb. 13, 1942. He had complained of a sore throat for the past two days, and on admission showed the usual signs of mild scarlet fever. The temperature was 100°, the rash was typical, and there was marked circumoral pallor. The throat was sore, with exudate on the tonsils, and some cervical adenitis was present. The next day his temperature was normal, and he made a rapid recovery from the acute stage. He began to peel on the thirteenth day.

On Feb. 25, 12 days after admission, the cervical glands became more enlarged and there was slight pyrexia. He was given sulphapyridine 2 days later, and the temperature became normal in 48 hours. The sulphapyridine was continued for a further 5 days until a total of 11 g. had been given. At the end of this time the swelling of the glands was much less and the general condition satisfactory. Two days after this, on March 7, his temperature rose again, but there were no signs or symptoms to account for it. However, 48 hours later a painful red swelling appeared on the dorsum of the left foot, extending from the base of the great toe for 3 in. upwards. This was 25 days after the onset of the rash. He was again given sulphapyridine. Three days later inflamed veins could be seen and felt extending from the inflamed area on the left foot up to the knee. The leg was oedematous below the knee, and the popliteal vein was tender. The tongue became furred and the boy looked ill. The next day the patient was better. The temperature was normal and there was less oedema of the left leg. A further 11 g. of sulphapyridine had been given, and the dose was reduced to 0.5 g. t d s.

Twenty-four hours later, however, on March 14, the temperature rose again to 100°. On examination the left leg was still improving, but the right popliteal vein was tender and there was obvious phlebitis of the superficial veins below the right knee. On the following day there was oedema of the right leg below the knee, and the right internal saphenous vein was tender below the groin. The temperature rose to 101° and the patient was seriously ill. Anti-scarlatinal serum, 3,000 U.S.A. units (B.W. & Co.), was injected intramuscularly. The next morning he was better, having had a good night, and his temperature had fallen to 100°. The left leg had recovered, but the whole of the right leg was oedematous. The girth of the middle of the right thigh was 2½ in. greater than that of the left. The right internal saphenous vein was tender and inflamed along the whole of its course, and there was tenderness in the right iliac fossa.

The patient by now had taken 33 g. of sulphapyridine since the beginning of his illness, and a blood count was made by Dr. Griffiths of the Kent County Laboratory. This showed: R.B.C., 3,860,000; Hb, 71%; C.I., 0.92; W.B.C., 15,800—polymorphs 90%, lymphocytes 7.5%, monocytes 2.5%. A blood culture proved sterile. Sulphapyridine was continued (3 g. a day), and on March 18 the girth of the right thigh was 3 in. greater than that of the left. The oedema had spread upwards over the right iliac fossa and the right loin. Enlarged superficial veins were seen over this area. The next day the patient was better. The temperature was falling and the tongue was getting cleaner. Three days later, on March 22, the temperature was normal and the oedema over the right loin and iliac fossa was much less.

On March 24 sulphapyridine was discontinued after a total of 41 g. had been given in 3 weeks without toxic effect. The patient was improving rapidly. The tongue was clean, and there was no pain or tenderness in either leg. The girth of the right thigh was only 3/4 in. greater than that of the left. A fortnight later all oedema had gone and the patient was very well. After a further fortnight's convalescence he was allowed to get up, having had a normal temperature for a month. He went home one week later, on April 28, having been in hospital 10½ weeks.

When seen on Oct. 7, 1942, he was in excellent health. The only complaint was an occasional feeling of "heaviness" in both legs, especially the right, but he was able to run and play games. There was no oedema, but the girth of the right thigh was still 1/2 in. greater than that of the left.

COMMENT

A case of thrombophlebitis migrans occurring on the twenty-fifth day after scarlet fever is described. The veins of both legs and the right external iliac vein were involved. Improvement was noted after the administration of antiscarlatinal serum, but sulphapyridine in the doses given did not appear to modify the course of the disease.

An Unusual Retrocorneal Phenomenon

The following note on an unusual occurrence may be considered interesting enough to warrant publication.

Having removed a foreign body from the *left* cornea of a man aged 33, my attention was drawn to his *right* eye, where I saw a bright pink globule of about 1.5 mm. diameter, situated in the middle of the posterior surface of the cornea, the eye otherwise being quite normal. On examination under the slit-lamp the globule had—to my surprise—disappeared, but instead there was a faint reddish glow at the limbus about 12 o'clock. When the patient was asked to lie down again the spot was seen migrating slowly from the limbus towards the middle of the cornea, and always rose to the highest point of the anterior chamber as the eyes were turned in different directions.

The patient's record card showed that he had attended the hospital in Sept., 1942, when a foreign body deeply embedded in the stroma of the *right* cornea was removed and perforation with escape of aqueous occurred. Prontosil ointment 1% was instilled and a pad and bandage applied. The eye developed a mild iritis but healed in a week's time. A month later the patient complained again of photophobia and irritation, which quickly settled.

It would appear that owing to the pressure of the bandage a small portion of the prontosil ointment was forced into the anterior chamber, where it remained undissolved and unchanged without causing any trouble or inconvenience to the eye up to date (eight months). Neither the patient nor his friends have ever observed this striking appearance, since it is not visible when the patient stands upright.

Newcastle-upon-Tyne Eye Hospital H. M. TIETZE, M.D.Vienna.

Reviews

PROBLEMS OF TRAUMA

The Pathology of Trauma. By Alan Richards Moritz, M D (Pp 386; 117 engravings 28s.) London: Henry Kimpton.

The name of the author of this work and of Prof. Wolbach, mentioned in its preface and elsewhere, and the illustrations depicting specimens in the famous Warren Museum, recall happy memories of a recent visit to Boston during this war, an academic sojourn in a famous hospital associated with Harvard University, and the privilege of meetings with the above two distinguished pathological savants. The mere mention of Harvard in connexion with this work is a sure hall-mark of its excellence; the assembling of the material contained in the book, together with the comprehensive bibliography, has for its purpose the lightening of the labours of clinicians and pathologists confronted with problems associated with trauma, and must be considered a timely contribution to the literature of this period of violence and force, which reign throughout the whole world just now.

This work is for the graduate rather than for the medical student, and is not likely to replace such popular textbooks of forensic medicine as Dixon Mann, Smith, or Glaister in the British undergraduate library. Those who have lived through the days of heavy air bombardment of this country will be gratified to find reference to the renal failure associated with crush injury of the extremities; and mention is made of the work of Bywaters and Beall, of Belsey, and of Patey and Douglas Robertson of Middlesex Hospital in this connexion. Blast injuries of the lungs have not escaped the notice of the author. There is an informative section dealing with the less well known subject of cardiac contusion, to which subject Moritz has himself made other contributions. One is glad to note that he has culled material from Sir George Makins's classical work on *Gunshot Injuries of the Blood Vessels,* which was based on that famous surgeon's experience in the South African War and the war of 1914-18.

An abdominal surgeon not unnaturally turns to those pages which deal with injuries of the abdominal viscera, and a certain surprise is felt at the failure to find amidst an extensive bibliography pertaining to traumatic lesions of this region any reference to the work and enormous experience of such British surgeons in the casualty clearing zone in the last great war as Sir Cuthbert Wallace, John Fraser, Hamilton Drummond, Owen Richards, H. H. Sampson, Gordon Bell, or Richard Charles. The total experience of these surgeons embraces a mass of material from which valuable information might surely have been gleaned.

The pathology of the ruptured intervertebral disk is included in the pages of the book, as might be expected of a condition which owes its recognition to the work of transatlantic surgeons. The section devoted to injuries of the female genital tract, including rape, occupies many pages and should satisfy the most critical medico-legalist or gynaecologist. There is a discussion as to a traumatic origin of hydrocele of the male tunica vaginalis, but no mention is made of traumatic rupture of vaginal hydrocele, a definite clinical entity which has attracted the notice of British and French writers.

The illustrations in the book are numerous; the microscopical reproductions are excellent and illuminating, and the diagrams are particularly helpful.

G. GORDON-TAYLOR.

INTERNAL MEDICINE: A MISCELLANY

Advances in Internal Medicine Volume I Editor, J Murray Steele, M.D (Pp. 292. 21s) London, William Heinemann

In previous reviews we have questioned the wisdom of books of this kind, which bring together topics whose only unity is their novelty. A man who tries to keep abreast of current literature —and we can imagine no other man reading a book of this kind—finds need of books to bring order and perspective into the many facts he has stored up or forgotten. Hence useful books must confine themselves to a single sector or allied sectors of the field of advance. The present book supplies something for all tastes and is therefore likely to satisfy none.
The ten different articles it contains deal with the Mille
tube, diabetes, the sympathetic control of the periphera
sulphonamides, urinary infections, influenza, hype
nephrosis, and riboflavin deficiency. Of these, the ar
the use of the Miller-Abbott tube in the diagnosis and t
of disorders of the gastro-intestinal tract by Osler
and on modern conceptions of arterial hypertension
and Corcoran, will be the most welcome to British
For they are by master hands and they deal with su
which the Americans have gone further than we, large
to the circumstances of the war. It was in 1909, ap
that Scheltema, "observing one of his barnyard fowl l
to complete the ingestion of a piece of string, the firs
of which had already traversed the gut and reappearec
successfully attempted the same feat on a child b
of a rubber tube. From this has developed a techniq
is of great value in the diagnosis and treatment of ob
of the small intestine and the proximal colon, and
more would have been heard in this country had
embryo Hunterian professors and Goulstonian lectu
preoccupied with other affairs of State. It must be
too, that the subject of hypertension is one that the A
both North and South, have made their own. F
Corcoran review the whole subject of experiment
tension in animals, the tests designed to measure
reactivity in man, and treatment by operation, by thi
and by kidney extract. The field is full of promise,
is still much spade-work to be done.

FIRST AID TO DIAGNOSIS

Symptom Diagnosis: Regional and General. By Wallace Mas
M D, M S Fourth edition. (Pp. 900. 50s cloth.) New
London: D. Appleton-Century Company. 1942

When a textbook, which is introduced with the spec
ment that "there is nothing original in the mate
only its arrangement, reaches its fourth edition it ha
justified itself. *Symptom Diagnosis* was originally
(and that is the correct term) by the late Dr. Wilfred
and Prof. W. M. Yater, and has now been carefull
by the latter. It is not designed for study but f
reference; not for the library but for the desk. Th

REGIONAL ANALGESIA FOR ABDOM OPERATIONS

Regional Analgesia for Intra-abdominal Surgery. With Special
to Amethocaine Hydrochloride. By Norman R James, L R C
D A. (Pp 57; illustrated 6s.) London: J and A Churchill

There is some evidence that local, regional, and spin
thesia are becoming rather more popular in this
there are certainly so many cases in which their
indisputable advantages that the technique of ac
tion should be of interest to every surgeon and an
Under the title *Regional Analgesia for Intra-abdomin*
Mr. Norman James has produced a booklet with the
concentrated into 57 pages. While many different a
be successfully used in this way, the author's pre
for amethocaine hydrochloride, which he claims giv
found analgesia and relaxation of at least three hours
without toxic effects. As in the case of many other a
agents, there are unfortunately several synonyms
product—pantocain, butethanol, decicain, pontocain
etc. For the sake of safety one would like to see l
to compel uniformity of nomenclature in these matt

The injection of the analgesic solution, in strengths of 1/1,000 and 1/2,000, is preceded by an intravenous administration of omnopon in sufficient dosage to produce "a light state of narcosis," in place of the more usual barbiturates. The technique advocated for the thoracic nerve block and the subsequent posterior splanchnic block is the orthodox one which has been widely tested and almost universally adopted as satisfactory. Certain modifications are described for use in special operations—e.g., cholecystectomy, nephrectomy, gynaecological operations, etc.—and several good photographs amply illustrate the technical details.

Although short, this book will give the novice enough information to enable him to start his experience of this interesting and important branch of anaesthesia.

Notes on Books

A Tropical Medical Manual, by Dr. PERCY E. TURNER, was prepared for the use of Salvation Army officers, and a third edition is published at 3s. 6d. from International Headquarters, 101, Queen Victoria Street, E.C.4. This little handbook gives useful hints for lay persons called upon to care for themselves or others in tropical climates when stationed far from a doctor or a hospital. The first part deals with general hygiene and simple preventive measures against disease and insect pests; a chart of physical exercises for the maintenance of fitness is included. The second section describes simply but adequately the more prominent features and treatment of the commoner diseases that may be encountered. The instructions are not meant to replace skilled attention, but should prove valuable to those so situated that they must rely upon their own resources.

A fifth edition of *Fevers and Fever Nursing,* by Miss EVELYN C. PEARCE, sister-tutor at the Middlesex Hospital, which appeared first in 1930, is published by Faber and Faber at 6s. Some alterations have been made and three new charts added to include information on diseases the danger of which is enhanced under war conditions—bacillary dysentery, undulant fever, and glandular fever—and also on the louse-borne infections, which are dealt with in a new chapter. Infective jaundice also forms the subject of a new chapter.

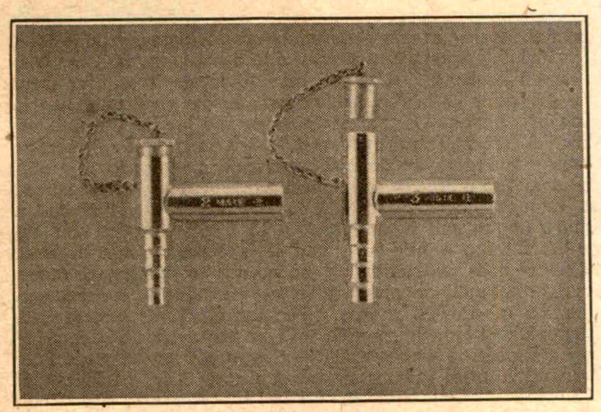
Dr. Julius Bauer's book *Constitution and Disease,* mentioned in our leading article entitled "The Constitutional Factor" on April 24, will be issued in this country during June by Heinemann Medical Books Ltd. at 21s.

Preparations and Appliances

A SUCTION ENDOTRACHEAL UNION

Dr. W. A. COBB, D.A. (Hurstwood Park Hospital), writes:

During endotracheal anaesthesia it not infrequently happens that mucus enters the tube and causes more or less embarrassment to respiration, the degree of which may be out of all proportion to the amount of mucus present, increasingly so with smaller sizes of tube. This factor may not be of much importance in short operations, but in the longer ones, and, in particular, intracranial and thoracic, it is of real significance. Much can be done, by proper timing and dosage of the pre-operative atropine or scopolamine, to reduce the secretion of mucus, but when for any reason this fails recourse must be had to endotracheal suction.



An endotracheal union, through which a suction catheter can be passed, is available, but is so cumbersome that it is only likely to be used when its need has been expected. My object has, therefore, been to make a union differing so little from the normal that its use could be routine, and suction could be applied to any case should the need arise.

The union is a modification of Rowbotham's pattern and is made in sizes 2, 3, and 4; size 1 is too small to allow the passage of a catheter. The vertical limb has been carried upward about 1/4 in. beyond its junction with the horizontal limb, and its upper end closed with a small metal stopper, attached to the union by a short length of chain. At any time during the operation this stopper can be removed and a rubber—or, if preferred, gum-elastic—catheter can be passed, and suction applied. Size 2 will take a No. 6 catheter, and Sizes 3 and 4 a No. 9. These three sizes of union can be used for all anaesthetics where an equivalent size Magill or Rowbotham union would normally be used. A further advantage is the greater ease of cleansing, owing to the absence of blind corners.

The unions have been made for me by Medical & Industrial Equipment Ltd., 12, New Cavendish Street, London, W.1. The photograph reproduced is about half natural size.

PELVIC BINDER

Dr. PAUL F. McGOEY (Canadian Orthopaedic Unit) writes:

This simple type of pelvic binder has been designed for use during examination and treatment of orthopaedic patients. It is small yet adequate. The material is towel cloth, and the string is standard orthopaedic cord (No. 6). Approximately one square foot of cloth and seven or eight feet of cord are required. The binder is easy to make, inexpensive, compact, readily laundered, and fits snugly and comfortably. It is tied with a single knot, does not impair movement, gives satisfactory exposure, can be applied over trousers, and is easy to remove from beneath plasters.

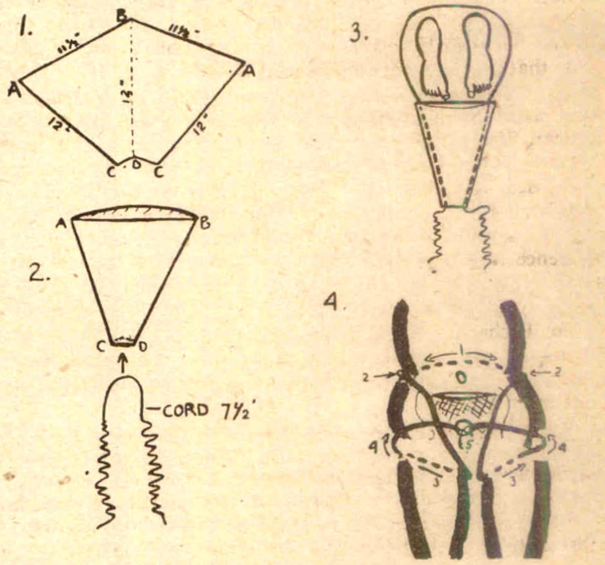


FIG. 1

The index to the diagram (Fig. 1) is as follows:

1. "Kite-shaped" pattern. Fold along line BD; sew AC to AC; leave AB and CD open so as to form a funnel-shaped bag as in diagram 2.
2. Insert hand into top open end (AB) of funnel, and draw through a loop of the cord sufficient to encircle patient.
3. Illustrates position of patient.
4. Binder in place: (1) Centre point of cord corresponds to midline posteriorly; (2) cord runs along the top of iliac crest and down through "funnel"; (3) cords emerge and encircle the buttocks in the gluteal folds; (4) cords pass around the hips; (5) single knot is tied in front of binder; technique of application can be modified to suit various positions of patients.

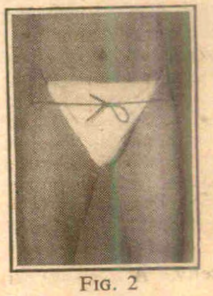

FIG. 2

I am indebted to Matron A. B. Hunter and Dr. L. M. Hampson for help in the preparation of this description.

Nova et Vetera

THE FIRST MEDICAL BULLETIN

Dr. C. E. Lakin, in his annual oration to the Medical Society of London on May 10, traced the first medical bulletin very far back in the world's history. The bulletin was an oral one, given, like Mussolini's pronouncements, from the window of a Roman palace; its author was a woman, and it was false. The wife of Tarquinius Priscus, the fifth of the early kings of Rome, had a female slave who gave birth to a son, and as there were flames around his head and other supernatural manifestations, the queen adopted him, and on reaching manhood he, Servius Tullius, married the king's daughter. The sons of the former king, Ancus Martius, whom Tarquinius had supplanted, resolved to seize the crown, and hired two shepherds to assassinate Tarquinius in his palace, which they did. Thereupon the queen ordered the palace to be closed, caused the shepherds to be arrested before they could escape, bade her adopted son Servius Tullius play the man, and herself went to the open window and declared to the Roman citizens that the king had only been stunned by a blow, that the weapon had not penetrated deeply, that the wound had been examined and the blood wiped away, that the symptoms were favourable, and that, the king having recovered consciousness, he desired that Servius should act for him until he was fully restored. By this clever bulletin, false though it was, she defeated the designs of her enemies, who, hearing that there was every prospect of the king's recovery, fled from the city, and by the time the king's death could no longer be concealed Servius was in unquestioned authority. The word "bulletin" in such a connexion is, of course, a comparatively modern use. Meaning an official statement as to the health of an invalid, it appears to date from 1765, when Horace Walpole wrote from Paris that the Dauphin (the son of Louis XV) was at the point of death. "Every morning the physicians frame an account of him, and happy is he or she who can produce a copy of this lie, called a 'bulletin.'"

MEIGS'S SYNDROME

Recently there have been a number of case reports of a syndrome comprising the combination of ovarian fibromata, ascites, and hydrothorax. The condition was first fully described by Dr. J. V. Meigs of Boston, and the syndrome has become known by his name.

Lawson Tait's Case

It is the purpose of this note to make more generally known another example of this syndrome described by Lawson Tait (*Trans. med.-chir. Soc.*, 1892, **75**, 109). The article is entitled "On the Occurrence of Pleural Effusion in Association with Disease of the Abdomen"; it has not been mentioned in any of the recent literature. There is first described a typical malignant case with ascites and pleural effusions from secondary deposits. His second case, by contrast, is of the non-malignant condition.

The patient was a lady of 36 years whose abdomen was noted to be becoming larger in June, 1889. This steadily increased—very rapidly during Dec., 1889. In Jan., 1890, there were an evident left hydrothorax and all the signs of ascites; on deep pressure through the fluid a large rounded solid tumour could be felt, apparently moored in the pelvis and floating freely in the ascitic fluid. Ninety-five ounces of blood-stained fluid was removed from the left pleural cavity, and a few days later fluid was found and aspirated from the right pleural sac; it too was blood-stained. It was thought that there was a malignant tumour in the abdomen with secondary deposits on the pleural surfaces, and she was sent home to die.

A fortnight after her return home her left pleural sac was again tapped, and 80 oz. of pale yellow fluid was removed. In Feb., 1890, the abdomen was tapped and 11 quarts of pale yellow thin ascitic fluid was removed. From this time until Feb., 1891, her abdomen was tapped over 30 times, from 8 to 14 quarts of clear yellow fluid being removed. The pleural effusions did not recur.

The patient was readmitted to hospital in March, 1891. On opening the abdomen a large quantity of ascitic fluid escaped. The tumour was found to be a large solid growth of the right ovary; on removal it weighed 2 lb. 2 oz., and was found microscopically to be a fibroma. Recovery was complete.

Lawson Tait remarks: "The lesson in this case is in my opinion a very valuable indication that no set of conditions in the abdomen, however apparently unfavourable, are sufficient to justify us in an absolutely unfavourable condemnation in any particular case."

Newcastle-upon-Tyne. R. B. Thompson, M.B., M.R.C.P.

THE STATUS OF THE NURSE

Lord Addison presided over a luncheon given under the auspices of the Professional Nurses and Midwives Conference, when the principal speaker was Lord Horder. In a general reference to post-war planning, Lord Horder said that his slogan was "Do it now," and this should apply to an endeavour on the part of the medical profession to raise the status of their nursing colleagues and to make the vocation of nursing economically attractive to girls of the type who were particularly suitable to exercise it. If girls could receive efficient training and the opportunity to pursue a profession which carried its proper prestige and afforded economic security for the future, something would have been achieved without waiting until "after the war." Paper planning was all very well, but were they not sometimes, Lord Horder asked, "more planned against than planning"? The State-registered nurse was the centre of the situation. Her career should be freed from embarrassment and obscurantism by making it perfectly clear to the public what distinct status was implied by the hall-mark of the State certificate. He suggested that there should be a roll of assistant nurses, and that in future no one should be able to pose as a nurse who was not either a State-registered nurse or enrolled as an assistant or student nurse. There were certain small special groups of nurses who did not come within either of these categories, and their particular cases must be considered. Dr. Haden Guest, M.P., in thanking Lord Horder for his speech, while confessing that he himself could not see beyond the armistice, suggested the greatness of the field which would await both the medical and the nursing services immediately after the war.

SALARIES OF NURSES IN SCOTLAND

The Scottish Nurses' Salaries Committee, of which Prof. T. M. Taylor is chairman, has issued a second report. This reprints much of the earlier one, now to be regarded as superseded (*Journal*, Feb. 27, p. 264), and recommends maximum salaries for matrons and sister-tutors (omitted from the first report) and salaries for all other nursing personnel except those in mental hospitals and public assistance institutions, and assistant nurses. The salaries recommended in the earlier report—namely, £40 in the first year of training, rising to £70 in the fourth year, when the student becomes State-registered, and £100 to £120 a year for staff nurses, and £130 to £200 a year for ward sisters—form the basis for those now suggested for nurses in other than general hospitals. In approved general training schools the salaries of matrons will be from £250 to £700 a year according to the size of the hospital, and of assistant matrons from £200 to £400. In general hospitals which are not training schools the salaries will be from £200 to £325 for assistant matrons and from £200 to £525 for matrons. Similar salaries with minor differences will apply in fever and sick children's hospitals. As an incentive to nurses to come forward for tuberculosis institutions the committee recommends salaries £5 or £10 higher than elsewhere. Salaries in maternity hospitals, too, are to be £20 higher, the additional sum being payable for the extra midwifery qualifications. These salaries are to be regarded not as minimum but as standard national scales applicable to the whole of Scotland, and should come into operation as from April 1 last.

MASS RADIOGRAPHY IN LONDON

The London County Council expects delivery in the near future of one of the transportable mass miniature radiography units for early detection of pulmonary tuberculosis in accordance with the Minister of Health's scheme. It is proposed to locate it at four places in turn—hospitals or health centres—two in the north and two in the south of London. In the early stages the use of the unit will be limited to the more urgent demands, but in time it will be possible to make extensive systematic examinations of selected groups of persons. The officer in charge will work in close collaboration with the borough tuberculosis officers. The cost of the staff and maintenance of the unit is estimated to be £2,100 for the year 1943–4, and £3,020 for a full year, and it is expected that at least 100 additional beds will ultimately be needed in respect of each mass radiography unit, involving a total expenditure for bed accommodation of £23,000 a year. The L.C.C., in agreement with the metropolitan borough councils, will be responsible for carrying out the assessment of proposed allowances to patients who are found to be suffering from pulmonary tuberculosis. The machinery of the tuberculosis dispensary will be utilized to the greatest possible degree in connexion with the inquiries, and the actual giving of financial assistance will be made through the dispensary organization.

"Operative" dental treatment—i.e., extractions, fillings, and gum treatment—is to be provided at all the larger Royal Ordnance factories. A charge of 2s. 6d. will be made for each visit irrespective of its duration, but the dentist will see workers only on the recommendation of the medical officer.

SLOW UNION OF FRACTURES

During the past year or so there has been more than one reference to the impression held by many that fractures are taking longer to unite than formerly. If this were true it would, under present conditions, be a matter for serious concern, for fractures exert a drain upon man-power both in industry and in the Services. Of greater concern is the quality of the functional recovery that fracture cases now show by comparison with those of former days, whether or not the rate of union is slower. About this we have as yet no satisfactory statistical evidence. So many of the statements on these matters are based upon impressions rather than upon facts that one hopes that many more statistical inquiries of the kind reported by Watson-Jones and Coltart[1] will be made available. These writers have investigated the rate of union in 804 fractures of the tibia and femur treated in the Royal Air Force and at the Liverpool Royal Infirmary, though not all of the cases were treated throughout by the surgeons of either.

A clear distinction must be drawn between the biological process of fracture healing and the modifications in this due to the methods of treatment used. There is little evidence that the biological conditions are any different now from those of thirty years ago. As there is little complaint about fractures other than those of the femur and tibia, the problem would seem to be a local one, which would hardly be so were there in existence any widespread dietetic or other biochemical error. Burns[2] thinks that the delaying factors came into force suddenly some years before the war—in fact in 1930—and naturally there has been a tendency to interpret this as being the result of a sudden change in methods of treatment. Skeletal traction and unpadded plaster splints are suspect. The introduction of the former goes back at least twenty years further to Codavilla and Steinmann. Although Hey Groves,[3] who did so much for the advancement of the technique of fracture treatment, was using skeletal traction in 1916, nevertheless it would seem still to have been somewhat of a novelty in London in the 1920's. The year 1930 coincides with the great wave of enthusiasm for pin traction and unpadded plasters popularized by Böhler in his book published the year before. In spite of this it would be very wrong to blame the great Viennese surgeon, whose writings and methods have been plagiarized by so many of us. What also happened about 1930 in this country was a reawakening of surgical conscience about the treatment of fractures—an awakening which the investigations of various committees, leading up to a recent British Orthopaedic Association memorandum,[4] show still not to be complete. There is no doubt that since 1930 there has been a more critical evaluation of results occasioned by the setting up of fracture clinics prepared to deal with the problem in a very thorough manner. Such critical study has meant that the standards of union have come more and more to be based upon radiological rather than clinical evidence. Furthermore, recovery has been regarded in terms not of the patient's discharge from hospital but of his ability to return to normal occupation. Such considerations indicate how difficult it is to compare the time factors and results of to-day with those of thirty years ago.

Watson-Jones and Coltart quote writings from this *Journal* of 1912 by Robert Jones[5] and others to support their strongly held view that uncomplicated fractures treated by simple manipulation and plaster are uniting as quickly to-day as in former years. The factors causing delay are interrupted immobilization, traction and distraction, infection, persistent angulation, too early weight-bearing, and loss of blood supply. In skilled hands operative reduction does not cause delay. The decision to use this method for unstable fractures should be made early rather than as a last resort. These writers state that the greater use of skeletal traction accounts for the recent increase in the frequency of slow union. Statistically we doubt the justification for this conclusion on the evidence that they have put forward; in fact it rather seems to be guesswork, for they have compared cases treated in this way only with others treated concurrently by different methods which cannot justify a comparison dependent on time. Whereas their figures, though small, indicate the very real danger of distraction, yet we are inclined to quarrel with the writers in condemning traction. Their figure of 32 out of 199 fractures of the tibia treated by traction is altogether too small for any satisfactory deduction to be drawn therefrom. And the figures for cases treated by traction show only a moderate definite trend as compared, for example, with the very much clearer trend, though in a smaller group, of cases treated by frank distraction. The figures for distracted fractures are certainly the worst. Presumably many of them were cases of special difficulty. The measure of such possible difficulty has not been adequately considered, nor is there any estimate throughout the work of the influences of age, type of patient, or quality of the surgical team controlling treatment. We suspect that some of the poor results may be related to this last factor, and that many of the bad results in fracture treatment are the consequence of bad fracture treatment. The lack of evidence in the report in relation to age and condition of patients is open to criticism, as it is apparent that the 804 fractures studied were only partially in one homogeneous group—namely, those in the Royal Air Force, and the number of these is not given. Nevertheless, the weight of evidence of Watson-Jones and Coltart is impressive. It agrees with the conclusions of A. W. Allen[6] that "the incidence of delayed and non-union appears to be less than is ordinarily supposed." In the same treatise Parsons and Wilson report the incidence of delayed union of the tibia in 61 cases treated by skeletal and adhesive traction to be 20%. The total number of fractures treated by all methods was 114.

It is worth noting that the bad results of fractures were exercising the minds of surgeons as long ago as 1912. A Fracture Committee of the B.M.A.[7] was sitting then, as in 1938. In 1912 it was not so much a question of slow union as of mal-union. It will surprise most people to read that of 3,000 fractures investigated no less than 42%, or 1,276 fractures, suffered from mal-union, of which 896 had bad function (i.e., 30% of the total). Even in the anatomically good results (1,736 fractures, or 58%) there were 160 cases with bad function. Of 3,000 fractures, therefore, the functional bad results numbered 1,056, or 35%. Hey Groves, discussing these figures in 1916, said: "They form a mine of information and an authoritative standard by which all subsequent fracture work can be measured and with which it can be compared." When more is known about the functional results of a similar present-day group of fractures we shall be in a position to judge how valuable modern methods are. It is to be hoped that further statistical inquiries will be made: it would not be surprising to find emerging from such an inquiry the fact that it is often the grosser errors of treatment and the faulty application of principles that in uncomplicated cases are the causes of slow union, mal-union, and poor functional recovery.

"IN THE DISCARD"

Just over two months ago a statement by the Secretary of the B.M.A. about the consultations to take place between the Government and the medical profession was published in this *Journal* (March 20, p. 359). It was said that an undertaking had been given that discussions would proceed not on the basis of any preconceived plan of the Minister's, but "from the ground." The meaning of this rather obscure phrase is now becoming clear. The Representative Committee during its brief two months of existence has met several times both as a committee and in discussion with the Ministry of Health. Quite recently it had placed before it a memorandum from the Ministry which made it plain just how far off the ground the Ministerial plan had got. Owing to an indiscretion on the part of someone who had attended the discussions, the lay press got an inkling of the Ministerial plan. The disclosure of one item in this made it impossible to continue concealing the rest. At a largely attended meeting of the Metropolitan Counties Branch on May 16 Dr. Charles Hill, the Deputy Secretary of the B.M.A., in a vigorous and well-marshalled speech, told the audience of the substance of the exchanges of views between the Representative Committee and the Ministry of Health. Those who did not read the account of the meeting in our *Supplement* for May 22 would be well advised to refer once more to last week's *Journal*. The suggestions that have been put forward are, of course, non-committal—that is to say, the Government is not committed to take any action on them. But they are committal in the sense that they show clearly the direction in which the Ministerial mind is moving and its conception of what should happen to the profession of medicine in this country. Put briefly and bluntly it is this, that medical men should cease to exist as freely practising doctors and should become instead whole-time employees of local authorities. If this happens, then doctors will no longer constitute an independent, learned, and liberal profession, but will instead form a service of technicians controlled by central bureaucrats and by local men and women entirely ignorant of medical matters.

As was to be expected, the Minister has rejected the idea that medicine should be administered by a corporate body. A special compartment of the present Ministry would be set up to run the show, with the Minister—a political figure with a high degree of insecurity of tenure —responsible to Parliament for the health policy of the nation. Professional advice at the centre would be secured by a Medical Service Council, three-quarters of whose members would be nominated by the profession. This would be a statutory body with the right to make public its recommendations and proposals and to issue reports. A Central Medical Board would have executive authority over domestic matters, and would act as an appointments bureau for the whole-time State salaried domiciliary service. At the periphery local authorities, for health purposes, would be grouped by means of joint boards. General practice would be based on health centres staffed by, say, a dozen doctors working on a whole-time, salaried, pensionable basis with no right to treat private patients outside the service: men who had been in practice for a given time before the beginning of the scheme could exercise an option for part-time service in it. Practitioners newly qualified would have no such option, but would be compelled either to enter the service on the whole-time basis or stay out of it. Compensation for loss of practice would be paid. After qualification and preliminary house-officer experience the doctor would enter the service at a salary of £400 a year, at which rate he would remain for three years, thereafter rising by yearly increments of £30 to a salary of £1,200 a year. Thus a man who qualifies at the age of 24 would not ordinarily be earning £1,200 a year until he is 46. The proposals for a consultant service are as yet vague, but the appointment of consultants and specialists would be by the local authority, and would be whole-time or part-time "according to circumstances."

The Representative Committee faced these proposals with dismay—dismay that the Government Department officially connected with health should treat the much-vaunted comprehensive medical service in such a parochial manner. The absurd anomalies of splitting up health functions among different Government Departments is, for example, to remain, and the mental health services are excluded altogether from the scheme. Locally, confusion is added to confusion. The joint boards to be set up are to be responsible only for some of the local health services —for domiciliary practice and certain hospital services. The health of the school child will be looked after by the local education authority. Rural, urban, and county borough councils will share responsibility for environmental hygiene. The possibility of unifying the administration of health services both centrally and locally is ignored.

As Dr. Hill said on May 16, "Why the hurry?" It appears to many that political expediency has dictated the hurried—and, from the profession's point of view, ill-considered—moves that have been made by the Ministry of Health, as a direct outcome of the Beveridge report. The least politically dangerous move would be to act upon Sir William's Assumption B. Is this an attempt of the Government to win quick popularity with an impatient electorate by saying: "We have nationalized the doctors, and so given effect to Assumption B"? Has the Minister not noticed that the word "comprehensive" appears before "health service"? It is more than probable that immediately this war is finished the public, especially those returning to civilian life, will take a lively interest in Assumptions A and C. If, under continued pressure of public opinion, the Government then finds itself compelled to give that security against loss of income which is at the basis of the Beveridge proposals, it will naturally have to keep a sharp eye on the amount of money going out of the Social Security Fund. An important item in this would be medical certification. It almost looks as though the Government wishes to gain absolute control of the general practitioner for at least one purpose—strict supervision of certification by the doctors. It is not surprising, therefore, that the Representative Committee informed the Minister and the Joint Parliamentary Under-Secretary representing the Secretary of State for Scotland on May 17 that further discussion on the basis of the Ministry's proposals would be unfruitful. Faced with the suggestion that a Royal Commission be set up to consider the whole question, the Minister agreed to withdraw the proposals, and observed that he was not bound to any time-table in the issue of a White Paper. He agreed to a re-examination of the whole position, and to look upon the proposals outlined above as "in the discard." This, we understand, is a term used in the game of poker. It is well to remember that cards in the discard are re-shuffled and find their way back into subsequent games.

CEREBRAL REACTIONS TO ANTISYPHILITIC THERAPY

Severe cerebral reactions during antisyphilitic therapy are fortunately rare but have a high fatality rate. Of these reactions the most important is so-called "haemorrhagic encephalitis." The name is not a good one, as the condition is mainly not inflammatory but rather one of increased permeability of the capillaries; in this it has features in common with purpura. Causation is unknown, but most observers agree that it is the toxic action of arsphenamine derivatives on the smaller blood vessels of the brain and possibly allergic in nature. Others consider that syphilis itself is the cause, but this is to some extent negatived by the observation that the condition has been recorded in other diseases treated with these drugs. Symptoms usually come on rapidly after the second or third injection, and are characterized by nervous irritability, headache, epileptiform convulsions, and unconsciousness. Treatment is likely to be successful only if energetic and undertaken without delay: venesection, repeated spinal fluid drainage, and injections of adrenaline are indicated—the last-named is probably the most important, and injection should be repeated as often as once every hour. The pathological features are congestion of the brain, with multiple haemorrhages and in some cases areas of necrosis. An increased protein content of the cerebrospinal fluid has been described, but otherwise the fluid is usually normal.

Two articles elsewhere in this issue record more or less typical cases. Halcrow describes a case which might be a textbook picture. He considers the cause to be a toxic action of the benzol radical on the capillaries and advocates the use of the term "haemorrhagic encephalopathy." Nelson and his colleagues describe 4 cases, 3 of them pregnant women, only one of whom recovered. They also regard the condition as due to a toxic action on the capillaries, but consider that syphilis itself cannot be excluded and that in pregnant cases toxaemia of pregnancy may be an additional factor. Thomas *et al.*[1] have reported 8 cases, 2 fatal, out of a series of 764 treated with massive dosage of mapharsen. It is generally agreed that haemorrhagic encephalitis occurs more frequently with intensive therapy than with the more time-honoured methods, but the fact that in the latter the condition usually comes on very early in treatment suggests that it is due to idiosyncrasy rather than to heavy dosage. Courville and Marsh[2] record 12 cases, in 7 of which multiple symmetrical foci of haemorrhagic necrosis were found and in one a gross haemorrhage into the brain; they regard the condition as due to a peculiar susceptibility to arsphenamine of certain blood vessels of the brain. In a case described by Lichtenstein[3] the parenchyma of the spinal cord was mainly affected—in fact a demyelinization. He regards the condition as due to sensitivity of the nerve tissues or the vascular bed to the arsenic. The demyelinization may be the result of vascular changes, but the author regards it as a direct poisoning of the nerves by the drug. This case appears to be in a different category from those already quoted.

Haemorrhagic encephalitis is fortunately very rare, occurring only once in some thousands of cases; all are agreed that it cannot be foreseen or provided against and that it may follow relatively small doses of arsenicals. Certain blood vessels of the brain appear to be susceptible to the toxic action of the drug, some individuals showing a particular idiosyncrasy. The walls of the capillaries give way, leading to haemorrhage and perhaps necrosis. The symmetrical distribution of the lesions bears out this theory. It is of interest to note that mapharsen, which is claimed to be generally so much less toxic than most of the arsphenamines, appears to be unduly so as regards this condition.

DIET AND TRINITROTOLUENE POISONING

The relation of diet to the manifestations of T.N.T. poisoning in human beings has not hitherto received close attention. If the results of animal experiments can be translated in terms of human reaction, some investigations recently carried out by Himsworth and Glynn[1] may make a most important contribution to the prophylaxis of T.N.T. poisoning in munition workers. In any case, they shed much light on the mode and site of action of T.N.T. in producing its well-known toxic effects. The development of toxic symptoms in rats after the administration of T.N.T. appears to depend to a remarkable degree on the nature of their diet: a high-fat diet is accompanied by severe symptoms and pathological lesions, while with a high-carbohydrate or high-protein diet these ill effects are slight or absent. The two most striking manifestations of T.N.T. poisoning in human beings—cyanosis and toxic jaundice—are not of course reproducible in rats, while the aplastic anaemia which has accounted for a certain number of deaths in T.N.T. workers is modified in rats into a severe erythroblastic hyperplasia of the bone-marrow. But lesions of the liver, comparable to those found in human cases of toxic jaundice, and the excretion of T.N.T. derivatives in the urine, point to a fairly close parallelism in the toxic process in both species. The "fat" diet on which the complete picture of chronic T.N.T. poisoning alone developed contained 50% of fat in the basic mixture, while the "protein" contained 60% of casein and the "carbohydrate" 90% of wheatmeal bread. The first and most striking manifestation of the toxic process was the appearance of a bright red pigment in the urine within half an hour of administration of T.N.T. mixed with the food. The composition of this pigment and its relation to the colourless pigment giving the Webster test in the urine of T.N.T. workers are uncertain, but the fact that it was absent from the urine of one animal with severe liver damage, just as the Webster test becomes negative when T.N.T. jaundice develops, suggests that the red pigment and the Webster chromogen may have a similar significance. The dependence of the appearance of the red pigment on the nature of the diet was shown by its specially prolonged excretion by rats on the fat diet. With very small doses of T.N.T. (0.01 g. per kilo body weight) none was excreted by rats on the fat or carbohydrate diet but a trace by those on the protein diet—a fact explained possibly by the diuresis always present on this diet and the consequent washing out of the pigment before it can be changed into a colourless compound. It is suggested that the pigment is formed at an early stage in the disposal by the body of T.N.T., and represents a dosage larger than the body can deal with.

The remaining features of chronic T.N.T. poisoning in rats are loss of weight, increased appetite, changes in the blood picture, hepatic lesions, and loss of hair. Loss of weight, in spite of a higher total food intake, was characteristic only of the rats on the fat diet, and, from experimental exclusion of other possible explanations, it is concluded that the fat diet in some way influences the animal's metabolism so that its ability to dispose of the T.N.T. within its tissues is impeded. The changes in the blood picture—a fall in the haemoglobin content, the appearance of normoblasts, reticulocytes, and polychromatic cells, and an increase in polymorphonuclear cells—were also more conspicuous in rats on the fat diet, while liver lesions were found only in these rats. The liver changes ranged from fatty infiltration to acute necrosis of the parenchymal cells. The severity of the lesion bore no relation to the amount of T.N.T. given, but a preliminary period of feeding on the fat diet appeared to predispose to the development of the more severe disturbances. Certain peculiar features of the incidence of hepatic damage similar to those in the incidence of toxic jaundice in T.N.T. workers were observed. Thus, there was a latent period between the administration of T.N.T. and the appearance of liver changes, and only very slight lesions occurred in rats surviving 30 days.

---

[1] *Clin. Sci.*, 1942, 4, 421.

It has already been suggested by Voegltin, Hopper, and Johnson that the absence of cases of severe T.N.T. poisoning among workers in a factory studied by them might be due to the good quality of the diet provided. The results of this investigation appear to point to the same conclusion, with the corollary that a diet in which fat preponderates to a great extent is not to be regarded as one of "good quality."

HEALTH EDUCATION FOR GIRLS

One of the first results of the publication of *Our Towns*, on which we commented in a leading article on May 8, has been to direct closer attention of those responsible for or interested in youth organizations to the training they give in hygiene and healthy living. The National Association of Girls' Training Corps in its leaflet No. 6 already provides for a course of lectures in hygiene, the first three of which, to be given by a doctor, are concerned with (*a*) the body and its functions: minor ailments; (*b*) the skin and its functions: common skin troubles; and (*c*) general questions about the maintenance of good health. Dr. Sarah Roberts of Bedford has sent us a copy of her own scheme of lectures in social hygiene for girls from 16 to 18. The lectures fall easily into three groups. First comes personal hygiene, which covers roughly the same ground as the first three lectures of the Girls' Training Corps. Then there come two excellent groups of lectures on public hygiene and social hygiene. Dr. Roberts says that there is more chance of women using the public health services if they learn the "whys and wherefores" when they are young. She therefore explains the functions of maternity and child welfare clinics, nurseries, and school clinics, and discusses the work of district nurses, health visitors, and welfare workers. Immunization and vaccination, milk- and water-borne diseases, fumigation and sanitation, and institutional provision are other subjects in this section, the object of which is to bring home to the girls the value of and the reason for all these social services. In the lectures on social hygiene Dr. Roberts deals first with family life, particularly with the position of the mother as the hub of that circle. The mother should, she holds, have at least an elementary knowledge of the child's mind and body from childhood to maturity if she is to understand children at all. Next comes development, which includes anatomy, and discussions on puberty, adolescence, maturity, etc., followed by talks on pregnancy and childbirth. The final subject is hygiene of the community, including healthy living to produce healthy children, venereal diseases, tuberculosis, etc. Dr. Roberts says it is her aim to impart some worldly knowledge to these girls which will be of use to them through life and help to reawaken a more urgent sense of social responsibility. She advises simple language, using as few medical terms as possible, and has found the girls interested and orderly. She concludes with the suggestion that a course of this kind might be included in the syllabus for day continuation schools.

HYPOGLYCAEMIA AND THE BRAIN

Histological study of the brain in six fatal cases of hypoglycaemic coma by R. D. Lawrence, A. Meyer, and S. Nevin[1] has led them to conclude that a process akin to anoxia is concerned in this condition. Three of their cases were in diabetics and two in schizophrenics—all receiving insulin treatment—while in the sixth there was an adenoma of the pancreatic islets. Though there was some difficulty in estimating the duration and intensity of coma in these cases, the condition seems to have lasted for periods varying from three-quarters of an hour to 17 days. The histological changes differed somewhat in accordance with this variation. In cases in which coma had persisted for 36 hours or longer the cerebral cortex had undergone necrosis in many areas, with disappearance of numerous nerve cells. Selective involvement of the outer or inner laminae composed of these cells was particularly noted, also involvement of parts of Ammon's horn, an area known from Spielmeyer's work to be particularly liable to ischaemia. The corpus striatum and, to a less extent, the cerebellum were also affected, but the brain stem tended to be spared. There was widespread degeneration of neurones that had escaped complete destruction. Where coma had been of shorter duration earlier stages of the degeneration were present. These observations agree with certain others previously described both in hypoglycaemic coma and in conditions known to be of an anoxic character. An outstanding difficulty in the past has been to decide whether the basis of the disturbance may be primarily vascular, or whether there is a more direct action upon the neurones. Lawrence and his co-workers point out that in depriving the neurones of the glucose which forms the sole substrate for their oxidative processes a suspension of activity leading to degeneration and necrosis is entailed. Anoxia is not, strictly speaking, a correct term for this, and they therefore suggest a new word—oxyachrestia.

RESEARCH IN INDUSTRIAL MEDICINE

The Medical Research Council has arranged with the London Hospital for the establishment there of a department for research in industrial medicine. Dr. Donald Hunter, physician to the hospital, has accepted a part-time appointment to the Council's staff as physician-in-charge of the department, and the Council will appoint research assistants to work under his direction. The hospital is providing accommodation and facilities, and will be responsible for the treatment of cases under investigation. The primary purpose of the department is to undertake clinical researches into disorders affecting industrial workers, including both occupational diseases and others of a more general kind. This work will be done mainly in the department itself, but the staff will make visits from time to time to other parts of the country where special problems for investigation may be brought to the notice of the Council. The department will also be responsible for teaching and instruction in the subject. This arrangement supersedes that made last year for the appointment of a whole-time director of research in industrial medicine attached to the Council's headquarters. This post had become vacant through the appointment of Prof. A. W. M. Ellis to the Regius Chair of Medicine at Oxford.

MEDICINE AND POLITICS

BY

GEOFFREY BOURNE, M.D., F.R.C.P.

In considering the future of Medicine in this country two separate and distinct issues are involved. One is the question of how adequate health services are to be financed; the other is the question of how they are to be organized and controlled. The former will obviously depend upon the economic state of the country after the war. A considerable extension of State financing will be necessary if and when direct payment out of earnings and voluntary efforts can no longer meet the existing needs or the increasing burden of essential future development. State financing of medical services may then be a duty and a benefit. But *political control* of medical practice and of medical science is another matter, and in my opinion this will always be unconditionally bad.

The Political and the Scientific Outlook

The politician differs from the doctor in training, qualification, and general outlook. The member of Parliament is trained for some activity other than the science of government, or else he is untrained. He is not qualified for his work by any necessary study of finance, economics, or even the technique of reasoning. The emotions of the populace are his guiding light, and it is dangerous for him to defy them. Playing upon the emotions is also the means by which he achieves his political ends. When political axioms are unpleasant or unpopular they may be disregarded or changed. The politician is often ignorant of science, and even if he is aware of the established scientific facts in such cases as diphtheria immunization or pasteurization of milk he is prepared to ignore them in order to avoid antagonizing vocal and ignorant constituents. "This might be the pate of a politician," says Hamlet, "one that could circumvent God."

The doctor, on the other hand, undergoes long, arduous, and intensive training, and his knowledge is thoroughly tested before qualification and practice. He has been taught to weigh evidence before forming conclusions, and knows that failure to act in accordance with scientific truth invites disaster. He learns to respect truth as such, and to value severe and unbiased criticism as a means of arriving at truth. Thus, a fundamental difference exists between political and scientific standards. Political policy is determined chiefly by opportunism and expediency; honest-mindedness and accuracy are essential in science. When scientifically trained individuals engage in politics they are usually forced by circumstances to judge issues by political rather than scientific standards. The science of medicine must never allow itself to be put in a position where its freedom is in the slightest degree curtailed by such political pretexts as the statement that a question of "policy" is involved. Complete freedom of speech, criticism, and medical practice must be retained. Any member of a State service must have the right to speak his mind about his political or professional superiors on any question of medical science, practice, or policy.

Science and Administration

The politician, in so far as he is altruistic, has one supreme aim—administration. To be a good administrator is his ideal. "The Administration," "the Executive," are self-explanatory terms. There is a connotation of supreme central power exercised through successive subservient grades. The politician, by adding "ad," has reversed the word's proper conception. He is fond of this minatory prefix; he adverts, he adheres, he adjures, and he admonishes. Ministration means service. Now, since what is unknown cannot be administered or ministered, the politician regards research as politically non-existent. Moreover, the political or electoral value of future discoveries is *nil*. The public attitude to scientific matters confirms the politician in his idea; for *vox populi vox Dei*. Medical service, to the man in the street, is something which can be "laid on, like gas and water." Politics can often be turned on like gas, but science cannot be turned on like water. Where uninstructed public opinion can directly influence medical organization, as in municipal councils, this blind worship of administration is shown by the fact that seniority in the medical services combines increasing administrative power, diminishing medical opportunities, and more pay.

The public, taught to worship and revere administrators, is prepared to receive their administrations without complaint at any given level of scientific ignorance. In 1920 hypothetical medical bureaucracies might well have stifled the research work which discovered insulin and the liver treatment of pernicious anaemia. In that case the public would have continued to die happily and respectably of these diseases with praises on their lips for the smooth efficiency of their bureaucrats. Medical discoveries are popularly regarded as dropping like ripe plums from trees. Politicians are prepared to exploit them when they do drop, but neither the politicians nor the public realize that a research worker requires adequate laboratories, freedom from interference, a completely fair intellectual field, and adequate remuneration. A scientific doctor has the same needs, and all good doctors try to be scientific. These requirements are not smiled upon by the administrator, for they fall into no preconceived pattern and smack of revolt and insubordination.

History proves that scientific freedom and research are of vastly greater importance to humanity than is administration. This is especially to be stressed because medical science is very young and has far to go. A bureaucratic medical administration may be highly efficient, but if it stifles initiative it will perpetuate the existing death rate of many diseases. Professional freedom, on the other hand, given the right atmosphere and opportunity, will reduce these death rates even if the administration is less good. Therefore, in terms of human lives, there is no doubt that the scientist is more valuable than the administrator. Innovators of all kinds are attacked by politicians of most parties; scientific innovators are equally attacked in medicine. But, in politics, the fate of the innovator may entirely depend upon money, newspaper influence, misrepresentation of facts, party combinations, or propaganda. In science the innovator is sooner or later accorded his rightful place when the truth or falsity of his claims is established by experiment, logic, and observed fact. The careers of President Wilson and of Lister provide significant examples of the two methods.

Concentration upon administration and lack of appreciation of real scientific needs are exemplified by the municipally controlled services, in which pathological and other special staffing is inadequate, except for bare routine. The voluntary hospitals, starved of money as they are, compare in these essential respects most favourably with their municipal sisters, who have, or should have, unrestricted financial support.

Intellectual activities are not encouraged by politicians. Education is the most important of all such activities, and the bureaucratic treatment of education by politicians, both in Parliament and in local councils, is of sinister omen. The initiative of teachers is damped centrally; they are poorly paid, and mercilessly overdriven as indicated by the size of classes in the pre-war period. The financial worth of the teacher to the community in many cases is assessed at a lower level than that of the bus-conductor.

Ideally, administration should decapitate itself and minister fully to science, thus allowing scientists and doctors full scope to serve the public. The great advances in American medicine in the last 25 years are probably largely due to the humble place generously and voluntarily taken by the administrators of such funds as the Rockefeller Trust. A similar attitude could be assumed by State ministrators in a British Medical Service. Wise generosity is a good investment.

The political risks inherent in State control of medicine are real enough when this is centrally directed. They become greater when the control is relegated to small local bodies. The local magnates, farmers, trade unions, and other interests will all bring pressure on the isolated medical bureaucrat. This latter, for the sake of the peace and quiet so desirable for steady Civil Service promotion, will almost inevitably try to keep his local doctors and scientists quiet and orthodox, and will tend to discourage those experiments and investigations necessary for advance in medical knowledge. In a State service the local liaison between the public and the profession should be designed to be non-political.

The muddle-headed thinker and the political fanatic will deduce or pretend that any criticism of politicians and administrators in this connexion is an attack upon the whole idea of State medicine. This is untrue and is founded upon false logic. The two issues, State financing of health services and autocratic political control over science, must be considered separately. A system which combines these is completely unacceptable. One in which science is free and finance is inadequate is better, for progress follows intellectual freedom. A system which combined financial support with complete intellectual and professional freedom would be ideal. If State financing of medical services is an economic necessity the wisest course would be to place it under a detached and sane body such as the Privy Council. In this way medicine might be saved from becoming the new electoral toy or the helpless prey of central and local party politics, and there would be some hope of preserving that individual initiative which both Mr. Herbert Morrison and Mr. Oliver Lyttleton have recently praised as being so valuable "in its proper place." No more proper place for this quality exists than medicine.

The medical profession can help to clarify the issue by determining solidly that, at all costs,

1. Medicine and science must not be political.
2. In any State service the administrator shall become the ministrator, the servant of the public and its doctors.
3. The profession must be controlled by itself—that is, democratically from within in respect of its medical affairs.
4. In any State service promotion must be by professional ability and not by seniority.
5. The public must not be fobbed off with a medical service which will be just adequate. The country must be prepared to pay for the best possible service.
6. Research and medical teaching must be intellectually free and generously financed.
7. Opportunities for reviewing and remodelling the system from within must be available.

The conclusion of this matter is of vital interest to all branches of science and therefore to civilization; for science is the sap of civilization. Medicine is the most powerful, politically, of any scientific activity. If it follows education into the political maw there will be little to prevent all other intellectual activities and freedoms from following. It is imperative, therefore, that freedom of scientific action, speech, and criticism be insisted upon quickly by all scientists, both for medicine and for themselves. The mind is greater than the body. Habeas Corpus was one milestone in human freedom; Habeas Mentem must be made the second.

Reports of Societies

NASAL ALLERGY

At the last meeting of the Section of Laryngology of the Royal Society of Medicine, Mr. V. E. NEGUS presiding, the discussion was on nasal allergy, excluding hay-fever.

Dr. **GEORGE BRAY** declared that the allergic nose accounted for at least one-third of the practice of the rhinologist. Allergy should be suspected in cases of persistent sneezing, running, blockage, and polyposis, especially if there was a family history of similar symptoms. In a person with allergic predisposition the first nasal discomfort usually occurred as a sequel to upper respiratory infection. The commonest time was early in the morning, following contact with a cold environment. The sequelae were cough, asthma, headaches, deafness, and formation of polypi. He gave the following list of specific sensitizing substances:

Inhalants: feathers and down, orris root, animal emanations, tobacco, dusts, drugs, insecticides, fungi, osmyls, and odours.
Ingestants: foods (wheat, eggs, milk, chocolate, tomato, nuts); drugs (aspirin, iodides, quinine).
Physical agents: cold, heat, light.
Infectants: bacteria rarely sensitizers
Non-specific irritants: strong smells, bright lights, tobacco smoke, petrol or oil fumes, sulphur fumes, chlorine in water.

Peeling new potatoes, cooking legumes, handling soap powders, and walking past a fried-fish shop had been known to induce attacks. Treatment should be primarily from the allergic aspect. General treatment comprised avoidance of fatigue and emotion, and irritants should be removed. Specific desensitization was of value; non-specific was useless. Among drugs, adrenaline, ephedrine, and benzedrine were useful; cocaine, menthol, and calcium should be avoided. Endocrines were often beneficial, especially thyroid in old people, and ovarian extracts at about the menopause. In surgical procedures conservatism was the keynote of treatment. Ionization was only temporary in its effects, and the value of diathermy and radium was questionable.

Pathological Aspects

Dr. **CYRIL POLSON**, after a brief history of the subject, discussed the findings in gastric analysis, blood sugar estimation, and liver function tests in allergy. Hypochlorhydria in these patients was usually associated with excess of mucus, and probably due solely to that cause. The mucus was more likely to be derived from the respiratory tract than from the gastric mucosa. A low fasting blood sugar concentration might occur in allergic patients, but the cause was not yet explained. Evidence of liver dysfunction in allergy was equivocal. Among naked-eye and microscopical appearances eosinophilia and oedema of the mucosa were the outstanding changes. The eosinophil leucocytes were derived from the bone marrow and conveyed to the nasal mucosa by the blood stream. The mononuclear type of eosinophil leucocyte was, for the most part, only a degenerate form of the polymorph cell. The cause of mucosal oedema was still unexplained, but oedema appeared to be an essential factor in the development of nasal polypi.

Lieut.-Colonel **MYLES FORMBY** said that the local manifestations of the clinico-pathological syndrome of nasal allergy often hid the dyscrasia which was the basic enigma, itself an anaphylactic phenomenon. About 400 cases of allergic rhinitis seen in the course of five years were analysed as follows:

	Males	Females	Total
Uncomplicated	48	67	115
With ethmoiditis	122	116	238
With polypi	29	14	43
Asthma (no nasal sign)	7	4	11

Allergic rhinitis had become increasingly common during the last ten years. Local infection played no important part until it had been grafted into the upper respiratory mucosa by surgical interference. It was then a secondary complication, not a fundamental aetiological factor. Under treatment he described a technique for applying radium to nasal polypi. It consisted of the application of 12 needles (6 on each side) for 7 hours, the dose being 546 milligramme-hours.

American Experience

Several officers in the U.S. Army Medical Corps gave their experience. Colonel **CANFIELD** said that in his American clinic the surgical approach was extremely conservative, and in very few out of 150 cases which he had taken was any major sinus surgery done. The congestion inside the nose had been relieved by removal of obvious polypoid material; and occasionally the ethmoid was opened if there was severe infection. In his view the polypoid condition occurred first, and then, because of obstruction, the nose became more susceptible to an infecting agent. Major **FOWLER** described allergic rhinitis as a manifestation of sympathetic or parasympathetic imbalance. Major **HOOPLE** said that the experience he had had with allergies had not been satisfactory enough to make him feel that these cases should be turned over to the allergist and discharged from the care of the rhinologist. Rhinologists must keep these cases in their own hands, realizing at the same time that they were cases of general disease. Captain **RICE** said that the simple fact was that not enough was known about this condition, and that by study of the local state not much more was going to be found out. Any more definite information was likely to come from the biochemist.

Mr. **MUSGRAVE WOODMAN** said that he had had good results from the old process of cauterization. Zinc ionization was not a cure-all, but many cases so treated went through the summer without hay-fever. He criticized Colonel Formby's use of radium. Colonel Formby put in a fairly large amount of radium for a very short time. The line now followed was to apply radium in smaller doses for longer time. He believed it most inadvisable to carry out any operation in the acute stage. Psychology was a very important factor in these cases, and he had had some good results from routine breathing exercises.

Mr. C. HAMBLEN THOMAS said that he had had some success with diathermy and also with intramuscular calcium injection. It did not, however, act in every case. Allergy was a peculiar condition and rhinologists must look to physicians and biochemists to help them out. The less they interfered the better. Dr. VERA WALKER suggested, on the basis of some dietetic studies, that a deficiency of eggs and milk might be a predisposing cause. Dr. T. B. JOBSON considered that these allergic cases were likely to get worse if inhalants were used. A common medication was mainly liquid paraffin broken up into very fine droplets which was inhaled into the lung, and after a time the alveoli became blocked up with fine particles, and a condition like silicosis occurred. During 15 years he had got better results from ionization in the nose than from any other form of treatment.

Major IRELAND had found some cases relieved by ionization. He did not like the idea of turning all these cases over to the allergist. Dr. F. A. PICKWORTH showed slides illustrating the eosinophilia in these cases. Dr. FRANCIS said that any operation which damaged or removed nasal mucous membrane made the patient worse. The most valuable surgical measure was submucous resection if there was a marked infection, but it should not be undertaken otherwise. Combined with nasal treatment, any measures which improved the circulation would be found to help in vasomotor rhinitis. Even by rubbing the back of the neck and the scalp the congestion of the nose was relieved.

Dr. BRAY, in reply, said that in desensitization it was usual for patients to react to several allergens. The patient was asked to avoid these as much as possible, but in the case of the more common allergens he was desensitized to the main substances to which he reacted. Nowadays concentrated solutions were used, adrenaline was added to the solution to prevent an immediate reaction, and the desensitizing solution was given several times a day. With this more concentrated and rapid course of injections the majority of these cases would improve.

Correspondence

Medical Reorganization: The Constitutional Position

SIR,—I attended the meeting of consultants and specialists at B.M.A. House on May 19 but was unable to stay long enough to ask a few simple questions which may have a profound bearing on the present situation. I should therefore be grateful if you would publish the following remarks and queries. There is no attempt to disparage the magnificent work done by the B.M.A. and its various committees; their deliberations and useful spade-work may prove invaluable in good time. For the present I should like to put the following up for consideration:

1. Did the demand for State control or drastic reorganization of the medical profession come from either the general public or the profession?

2. As the answer to the foregoing is clearly "No," has the present House of Commons any mandate to introduce legislation of this very advanced nature without reference to the electorate?

3. Is not the main feature of totalitarian rule the planning of the lives of the community on important issues without reference to the wishes of the populace?

4. Is not the present Parliament (elected on totally different issues, years ago, and only tolerated as a wartime emergency) proceeding far beyond the powers which are intended by the Constitution of this country in attempting to introduce such controversial legislation without reference to the electorate?

5. Does any emergency exist to demand the hurrying on of this legislation in such abnormal times? Would it not be more rational to postpone action until an already overworked profession has time and opportunity to determine its own rights and future calmly?

6. Has the subtlety of the way that this has been presented by the Government been realized? Have we not been told in fact that unless we devise some scheme for reorganization of the profession the Government will present its own scheme which we shall *have* to accept? Have the implications of this been grasped? If we do prepare such a scheme and submit it, cannot the Government then turn round and say, "We are forcing no legislation. Why, here is the doctors' own idea of a scheme for a State Medical Service"? By this means they could present an apparently constitutional case for a State Medical Service in the absence of an electoral mandate. "*Here are the doctors' own proposals!*"

7. Is not the wartime habit of unquestioning subservience to all legislation being used as a lever to make us believe that all proposals of the House of Commons are inevitable? Is this really the case in matters not relating directly to the war effort? Have we already undergone that degree of "Nazification" or does the chance still remain for us to cling on dearly to our constitutional rights? Is that not what this war is being fought for, and if we do not keep those rights does it matter very much which side wins?

8. Does anyone seriously suggest that the opinion of men on active service or with the Forces, living under abnormal wartime conditions, can really be regarded as their considered opinion of the future? Are not they and those now studying medicine the main portion of the profession whose whole future is at stake and which is being decided in their absence?

9. Would not any sane person say, "*Plan now, deliberate now,* but for the love of Heaven don't attempt to *legislate* in this paranoic atmosphere"?

10. Finally, as an old and ardent supporter of and worker for the B.M.A. I am bound to ask this: If it comes to a question of actual negotiation with the Government, has the B.M.A. any concrete sort of mandate from the profession as a whole to act on its behalf? I submit that before the profession is committed in any way it will be necessary to see that every doctor has an opportunity of voting individually on the proposals. Is not the whole question of handing over our profession to the State far too serious an issue to be handled without a proper referendum of our own? And if we are handed over to the State how shall we criticize the administration of affairs by officials? This is a very necessary procedure on occasions, as in the recent diphtheria prevention campaign, when, in the early stages, the Ministry of Health committed almost every conceivable major blunder because of the inexperience of its advisers on most of the practical and some of the technical issues. These howlers it was my privilege as a private independent worker to attack, and they have all been rectified. But who can expose idiocy when we are all in the asylum under the care of a loving keeper?

If any who read this letter should see any sense in my contentions and queries, would they draw the attention of others to the matter? There might even be food for thought as regards resolutions at Division meetings and queries to M.P.s on the constitutional issue.—I am, etc.,

London, S.E.5 GUY BOUSFIELD.

A Problematical Future

SIR,—As one no longer interested personally in the practice of medicine, but deeply concerned with the future of the profession, perhaps I might be allowed to place on record my views with regard to the Beveridge plan, so far as it affects medicine.

In a professional life which embraced the club system and the National Insurance Act (the latter of which I heartily sponsored), I have always regarded as a high privilege being to a certain extent my own master, and it is for that reason, among others, that I should advise a very careful consideration of all the implications which an acceptance of the scheme would involve. I willingly embrace the thesis that the welfare of the patient should be our first consideration, but I am not prepared to admit that his treatment will be materially better under the scheme than that afforded at present. In actual practice I have not found that team work—which is a feature of the scheme—yields better results than individual care coupled with invoking other advice when necessary.

Be that as it may, there can be little doubt that in the case of the seniors in the profession their financial position will be definitely worsened, though I would not stress that objection as being fundamental. Should there be any doubt on that point, it is only necessary to consult *Whitaker*, where the incomes enjoyed by civil servants in comparable positions to those prepared to work the scheme will be found less attractive than those enjoyed by the bulk of the profession to-day, and such amenities as pensions and liberal holidays will lose much of their attractive appeal.

Sir William Beveridge seems to show a disarming ingenuousness when he proposes to give substantial sickness allowances. No doubt in a guileless world this might be feasible, but in a world where "lax" certification is not unknown and the reluctance to return to work is, it points to a lack of knowledge in dealing with this aspect of the question. If we feel dissatisfaction on this point on which medical men can feel sure of their ground, a certain reluctance to accept his authority on other points not so accessible to us is not unreasonable.

I would therefore submit that we should be extremely chary of abandoning our present liberties for a chimerical future. To surrender the "glorious privilege of being independent" is not lightly to be undertaken. And above all let us remember that a decision once taken is irrevocable. There is no turning back.

> "Facilis descensus Averno,
> Sed revocare gradum . . ."

—I am, etc.,

Cheadle Hulme H. ELKINGTON SMITH.

Planning of Medical Education

SIR,—Prof. Francis Davies's article on the planning of medical education (May 1, p. 547) contains some excellent features, but certain suggestions must not pass without a challenge. Many of us will endorse his statement that "the better students take the present curriculum in their stride." It may be true to say "that too high a proportion are not up to the standard required." It is most certainly true to state that we have no desire "to bring down the standard or scope of the various subjects to the level of such students." Why, then, does Prof. Davies wish to dispense with the Second M.B. examination? Does he hope to raise or even maintain the present standard by such means? We are all painfully aware of the student, described by Prof. Davies, who can deal with his subject in small doses and yet is completely at sea when asked to correlate one fact with another. Surely the Second M.B. examination should be retained in its entirety if only to eliminate this very poor type of candidate as early as possible.

I cannot imagine anything more demoralizing than to require students to dissect the body in parts (which are purely arbitrary anyway), to examine them in detail on each separate part, and then to inform them officially that they can now forget what they have learnt. Are we never to test the student's powers of co-ordinating the anatomy of the body as a whole? By such a procedure, we are told, "we could get rid of the premium at present placed on mere feats of memory." Would Prof. Davies please tell us who *is* placing a premium on such feats? If he is referring to the present-day examiner in anatomy it is a most serious reflection upon his colleagues and one likely to be hotly challenged.

Surely Prof. Davies is a little out of date in asserting that students are allowed "to descend from degree to diploma" and to "crawl along the curriculum." I would remind him that in these days every student, if he is to retain his place in the school, has to be certified periodically to the Ministry of Labour as making satisfactory progress. It is our bounden duty to see that we do not return to the bad old days after the war.

Among the reforms advocated by Prof. Davies is one stating that all candidates for entry should be interviewed by a committee "comprising representatives of all faculties," whose duty would be to examine the candidate, his history and achievements in some detail. Does Prof. Davies realize how long such an investigation takes per candidate? From my own experience I can state that it cannot be accomplished in less than 30 minutes. By the time the committee had worked solidly from 9 a.m. to 1 p.m. and from 2 p.m. to 5 p.m. they would have examined precisely fourteen candidates. If the selection is to be really worth while, then at least three times the number of candidates to be admitted would have to be interviewed. Thus for a school admitting 100 students Prof. Davies's committee would be in continuous session for rather more than four weeks. I can well imagine that Prof. Davies's enthusiasm would stand him in good stead in such trying circumstances, but his colleagues from other faculties might be excused if they alternated between irritability and lethargy. Has Prof. Davies faced the possibility of his colleagues demanding a *quid pro quo* for *their* entrance problems?—I am, etc.,

Birmingham C. F. V. SMOUT.

The Diet in Diabetes

SIR,—May I thank Dr Micks (May 15, p. 598) for his very welcome ventilation of this subject of diabetic restrictions. So far as I know it has never been shown that a high blood sugar *per se* ever did anybody any harm. Of the common complications, coma is now accepted as being due to ketosis, and arteriosclerosis is not unconnected with lipid metabolism. The lowered resistance to infection is often alleged to be due to a raised tissue sugar. May it not be caused by impaired blood supply and nutrition?

For the past three years I have treated all my diabetics by restricting their fats to some 50 g. per day. Otherwise they eat what they like. They are given sufficient insulin to abolish ketosis, maintain weight, and reduce their glycosuria to reasonable limits. They are seen at intervals and carefully watched for acetonuria. Moderate glycosuria is acquiesced in. So far they all remain well. Their insulin requirements tend to drop rather than rise. They are much happier, a not unimportant point. My only difficulty is to explain why I will not permit them to eat fat when the Government allows them an extra butter ration!—I am, etc.,

Portsmouth J. C. PRESTWICH.

Calorie Control Diabetic Diet

SIR,—The active correspondence elicited by the article of Dr. A. C. Crooke and Miss Ella Scott (Jan. 16, p. 64) on the "new" principle of caloric regulation in diabetes has apparently ignored the fact that the Rockefeller Institute monograph which I published with Stillman and Fitz in 1919 was entitled "Total Dietary Restriction in the Treatment of Diabetes." The powerful influence of total calories and body weight was established by animal experiments and clinical studies before the discovery of insulin. This law afforded control of cases which had never been controllable by restriction of sources of glucose alone. It is not invalidated by accidental fluctuations of tolerance in mild cases, or by the slowness with which the bad effects of caloric excess become manifest in such cases. That it was also not affected by the observations of Newburgh and Marsh, Petren, and other advocates of high-fat diet is shown by two facts. First, in the original Newburgh-Marsh publications it will be noticed that only the relatively mild cases in older patients were dieted with high fat, and the severe cases were actually on low calories. Likewise, no one else has ever taken a series of cases which were severe according to our standards in the Rockefeller and Physiatric Institutes and kept them controlled for years without insulin on high caloric diets. Secondly, the slower influence of total calories and body weight in milder cases is so potent under right methods that Newburgh has now gone further to the opposite of his former position than most clinicians can follow, by asserting that mild diabetes with marked obesity often is not a true diabetes, or can be actually cured by reduction of total diet and body weight.

Immediately after the advent of insulin the varying insulin requirements resulting from alterations of protein, carbohydrate, fat, total calories, and body weight were demonstrated precisely in the papers published by Sherrill and myself in the *Journal of Metabolic Research* for Nov.–Dec., 1922, and Jan., 1923. In short experiments the glycosuric and hyperglycaemic effect of carbohydrate is predominant. In the long run the extra need for insulin with high carbohydrate in comparison with an isocaloric diet with low carbohydrate is relatively slight, as we proved with carbohydrate allowances up to 250 g. Later this fact was "discovered" and abused in the period of excessive carbohydrate diets, which are feasible but usually inconvenient and productive of undue blood sugar fluctuations. On the other hand, if most of the carbohydrate in any diet is replaced by its glucose equivalent of fat, thus greatly increasing the total calories, the immediate result may be a slight fall in insulin dosage, but as the body weight gradually rises the insulin requirement becomes increased and may finally be multiplied. In suitably prolonged tests the insulin requirement created by the most extreme disproportion of carbohydrate is trivial compared with the huge requirement created when a severely diabetic patient is fattened by a long-continued high caloric diet of either high or low carbohydrate content.

Insulin has covered a greater multitude of sins and fads than any other known remedy. The dietary principle of total caloric regulation furnishes the basis for an elastic and efficient control of all types of diabetes, with adaptation to the need and comfort of each individual. An explanation of the puzzling scientific fact may be opened up by the experiments of C. N. H. Long (*Proc. Amer. Diabetes Ass.*, 1942, **2**, 99). The fact itself—namely, the demonstrated predominant role of total calories and body weight and the relatively minor influence of total glucose value of the diet—has stood unshaken since the decade 1914-23, and can be confirmed by anybody who chooses to repeat our early experiments.—I am, etc.,

New York City FREDERICK M. ALLEN.

Aviation Medicine

SIR,—May I write in defence of my book on *Aviation Medicine*, which your reviewer (March 6, p. 287) does not like and on which he has, so I believe, not fairly reported? First of all, he has failed to say that, in contrast to existing textbooks of the same title, my book is not addressed to the medical specialist of aviation but "to members of the Air Forces, medical men, teachers, and everybody else who takes an intelligent interest in flying." At the time of writing my book such a publication was not in existence. There is, of course, an urgent need to acquaint lay people, and more particularly flying personnel of the Air Forces, with certain aspects of aviation medicine. This became obvious to me first during the years before the war when I was actively engaged in flying, and this conviction was emphasized during the first two years of the war when I had to give lectures on aviation medicine in various Air Force camps in this country. More recently I have devoted my time exclusively to physical education, being the medical consultant in this subject to the Northern Command of the South African Defence Force. But I am, as no doubt you are too, aware that the need for supplying air crews with information on medical aspects of flying has now been generally recognized by virtually all Allied Air Forces. Thus I think there is room for a book written for this purpose presenting aviation medicine in a form which non-medical men and medical non-specialists will understand. I have good reason to believe that many air crews as well as medical officers consider that this aim has been attained.

It appeared to me that a bibliography should not be attached to such a book, a point for which your reviewer has taken me to task. Writers like H. G. Wells, Julian Huxley, and Hogben, who also hold that technical information is not the monopoly of the specialist but that it should be placed at the disposal of those who apply it as well as of the ordinary man in the street, have done likewise. No apology is needed for not referring to "knowledge which has accumulated in the past four years, but which will not be available for publication until after the war." I considered, and still consider, it essential that a book of the kind I have written should be available to our flying men *during* this war. Books for the "more conservative" ones who wish to read about all scientific experiences collected since 1939 will undoubtedly be published after the war is won.—I am, etc.,

Johannesburg E. JOKL.

Indian Army Medical Corps

SIR,—In the article on the foundation of an Indian Army Medical Corps (May 8, p. 575) there is the phrase "slow-moving East," which apparently means that there is some characteristic in the Eastern climate and in the people there which is responsible for the delay in the institution of this medical body for the care of troops. A reference to the report of the Royal Commission on the Administration of Expenditure of India, 1896 (vol. 1, p. 378), will show that Dr. K. N. Bahadurji in his evidence advocated the formation of an Army Medical Service and a separate Civil Medical Service on grounds of economy and efficiency. The Indian Medical Service (I.M.S.) was, in the words of the letter of the Government of India, primarily military, whose officers were lent to the civil medical department to fill all the higher-grade posts in colleges and hospitals, and who were to return to military duty when wanted by the Army Department, and not, as you say, "originally a civilian service which provided doctors for the Army."

This matter was referred to by me in letters published in your columns and by numerous questions through friends in the House of Commons in the time of Lord Morley and Mr. E. Montagu. It has also been brought to the notice of the Government in the public press and on platforms in India. The opposition to this reform came from the India Office. You had neither the good will nor courage in those days to support the efforts of Indian doctors; you were under the influence of I.M.S. officers of the Military and Naval Committee of the B.M.A. It is gratifying, therefore, to see a departure from that policy of reserving the higher-grade appointments on the civil side for military officers. I see, also in the *Journal* of May 8 (p. 583), that Dr. S. R. Naidu, a civil doctor, is chemical examiner to the Government of Madras, a post which was before reserved for I.M.S. officers. —I am, etc.,

London, S.W.12 V. P. GONSALVES.

Abortus Fever

SIR,—Dr. Alasdair McI. Smith (April 3, p. 425) refers to the "almost certain" increase in the incidence of abortus fever in the human population as a result of the vaccination of non-pregnant cattle with living vaccines of *Br. abortus* and to the policy of the Ministry of Agriculture concerning vaccination. A statement of this kind may lead to a serious misapprehension of the position.

In cattle naturally infected with contagious abortion (*Br. abortus* infection) there is a tendency for the organisms to become located in certain organs, including the udder, with the result that the milk of such animals often contains virulent *Br. abortus*. The disease is so prevalent among cattle in this country that, generally speaking, it is impossible to control it by methods of segregation. There is, however, a growing volume of evidence in the United States, in this country, and elsewhere that it can be successfully controlled by immunizing cattle with vaccines prepared from living cultures of *Br. abortus*. There is as yet no satisfactory evidence that equally successful results can be obtained with dead vaccines. We are, in fact, in the same position in controlling contagious abortion in cattle as in controlling small-pox in man: we have to use living vaccines prepared from strains of attenuated virulence.

The Agricultural Research Council, following an extensive series of trials in cattle and an examination of the evidence in this country and in the United States, has recommended that two specified strains of *Br. abortus* should alone be used for the preparation of living vaccine. The Ministry of Agriculture is now producing vaccines from these strains for use in the scheme for the control of diseases of dairy cattle, and also, to a considerable extent, in the control of contagious abortion in herds not included in the above scheme. Long experience has shown that these strains are of such a reduced virulence that they neither set up the disease in cattle nor render them infectious, but they retain their immunizing properties. This state of reduced virulence is maintained by the method of preservation adopted.

A large number of careful experiments have failed to give any evidence that either of these attenuated strains, after injection into cattle, is excreted in the milk. From the public health point of view the position is, therefore, as follows. If these vaccines are not used the public run the risk of drinking milk infected with fully virulent *Br. abortus*. Where the disease is controlled by the use of these attenuated vaccines this risk is considerably removed. It is not even replaced by the much smaller risk of drinking milk infected with an attenuated strain. In view of these findings the Ministry of Health approved the use of these vaccines, and last year amended the conditions of the Milk (Special Designations) Order so that it is now permissible to vaccinate with these vaccines cattle in T.T. herds in which *Br. abortus* infection is present.

It will thus be evident that far from there being a likelihood of an increase in abortus fever following the use of *Br. abortus* vaccines issued by the Ministry of Agriculture, the resultant control of contagious abortion in cattle by this method should go a long way to minimize the risk of infection in the human population.—I am, etc.,

Weybridge. T. DALLING.

The Contaminated Injection

SIR,—Your article "The Contaminated Injection" (May 15, p. 608) raises a new point in this vexed matter of the dangers of infection by hypodermic injections. I have enjoyed immunity from any kind of trouble in this connexion for 20 years, during which a very great number of all kinds of injections have been given, and I attribute this to a routine by which the asepsis of syringes and needles is maintained with certainty. The evidence of aerial infection is particularly disquieting, for it obviously raises a legal point of great importance.

Since it is authoritatively stated that the introduction of air into a phial, the contents of which are to be injected later, *may* be dangerous and even fatal, it seems to me that in law a prima facie case of culpable negligence would lie against any registered medical practitioner who used for injection any preparation kept in bulk. It is plain that, no matter what precautions are observed, any phial can become infected by the inevitable entry of air (through the needle hole in the cap) due to the reduction of pressure within the vessel which results from the withdrawal of fluid into the syringe. This air entry being a fact, it follows that anyone using that phial for a second injection does so with full knowledge that its contents may be infected and dangerous, and I do not see how he could possibly rebut a charge of failing to exercise "a reasonable amount of care." It thus appears that the only thing we can do is to cease to use preparations in bulk and confine ourselves, as many of us already do, to sealed ampoules containing single doses.—I am, etc.,

Sunderland. A. KEFALAS

Calcium Intake in Pregnancy

SIR,—It is a pity that Dr. H. M. Sinclair did not immediately retract or modify publicly the brief extract of his paper reported in a January issue of this *Journal*. Like Dr. Sinclair, I also have had to write to colleagues, since the abstract of his paper appeared, emphasizing the importance of a high calcium intake in pregnancy.

As stated in my previous letter, I have been unable to trace any work which supports the belief that a *high calcium intake* prolongs either pregnancy or labour. *The abstract of Dr. Sinclair's paper dealt specifically with this aspect.* Abel's work, which Dr. Sinclair cites, refers not to the *intake of calcium* but *to vitamin D*. It is important not to confuse their different actions.—I am, etc.,

J. DOUGLAS ROBERTSON.
Courtauld Institute of Biochemistry, Middlesex Hospital, W.1.

Pertussis Antigen

SIR,—In your issue of May 8 (p. 562) Dr. R. S. W. Baker gives a summary of his results in the treatment of whooping-cough with Lederle's pertussis antigen. A personal experience in my own family, using this preparation as a prophylactic, may be of some interest.

About the middle of May, 1942, I gave two injections of 0.5 c.cm. at an interval of one week to my son aged 2 years. (The recommended prophylactic dose was three injections of 2 c.cm. at weekly intervals, but I thought I would reduce the dosage.) Towards the end of the second week the boy developed a cough which became spasmodic by the end of fourteen days. At the beginning of June I took my family to Scotland, rejoining my daughter, aged 3½, who had been evacuated there since November, 1940. During the first week of June the boy's cough became more severe and he vomited frequently after coughing. He had a mild attack of whooping-cough which lasted about fourteen days. We returned after three weeks, the boy being almost over the illness. Within ten days I learned that the girl had a severe cough, which in another few days proved to be a moderate attack of whooping-cough. She was ill for a period of six weeks and lost considerably in weight.

There are no other children in either household, the girl living with her grandparents, and the assumption was that the girl had been infected from the boy. Her illness was much more severe. The method of infection could not be proved, but the evidence was rather presumptive of the potency of the pertussis antigen.—I am, etc.,

Birmingham. A. WILSON RUSSELL.

Treatment of Malignant Tertian Malaria

SIR,—Dr. J. E. Murray (May 15, p. 613) seems surprised that the case recorded by Drs. W. L. Anderson and D. B. Bradshaw (April 24, p. 508) had responded to quinine. The League of Nations Malaria Commission has already pointed out that the strains of *P. falciparum* vary in different places, and that the West African strain is the most susceptible to quinine therapy. How susceptible is not generally realized, especially by doctors who deal with the resistant types elsewhere.

In 1928 I was accompanying a patient convalescing from hyperemesis gravidarum from the Gold Coast to England. The morning we sailed the patient developed a temperature and large numbers of *P. falciparum* were found in the blood. That night, on board, 6 gr. of quinine were given intramuscularly, and this was repeated in 48 hours. No further treatment was given on account of the hyperemesis. The patient made a complete recovery (on 12 gr. of quinine), and has had no recurrence of malaria.—I am, etc.,

Epsom O. G. WILDE.

Direct Inguinal Hernia

SIR,—I was interested in Surg. Lieut. M. R. Ewing's letter (May 15, p. 612) describing a special type of direct inguinal hernia, as I have recently encountered a similar case. The patient was a man aged 61 admitted with a strangulated right inguinal hernia, which was diagnosed pre-operatively as being of the indirect type. At operation it was found that the hernia was of the direct type, the sac protruding through an oval opening (1/2 in. long and 1/4 in. wide) in the fascia transversalis, the strangulation being caused by the narrowness and inextensibility of this opening. The bladder did not form part of the wall of the sac in this case. After reducing the hernia and excising the sac, a repair was made by suturing the opening in the fascia transversalis and uniting conjoined tendon with Poupart's ligament. He made an uneventful recovery.

In view of the mechanism of this hernia, strangulation should be a common complication. However, I can find only one reference to strangulation in the literature—one of Mr. W. G. Gill's cases described in the *Journal* of Feb. 11, 1939 (p. 263), was a strangulated Richter's hernia.—I am, etc.,

Liverpool. R. A. C. OWEN.

Interstitial Emphysema during Labour

SIR,—Mr. Vaughan Pendred's remarks on a case of interstitial emphysema during labour (May 8, p. 582) are interesting, especially the passage that a Queen Charlotte's consultant who was called in to see the case declared that he had never seen the like, thereby showing how rare the condition is. When resident medical officer at Queen Charlotte's Hospital in 1914 I published a case of this condition in the *Lancet* (1914, **2**, 445) and therein gave the cause of the disability as explained by the late Sir Francis H. Champneys. The emphysema in these cases is due to rupture of an air vesicle on the anterior surface of the root of the lung, the air escaping under the pleura into the anterior mediastinum and then up beneath the cervical fascia to the neck and chest.—I am, etc.,

Hendon, N.W.4. EDWARD SMEED.

SIR,—Your correspondents have recently drawn attention to cases of interstitial emphysema occurring during labour, and the suggestion was made by Dr. Phillips (May 1, p. 552) that it might result from the entry of air into the tissues of the face through a rent in the lining of the lacrimal duct. I do not think the association is unduly rare, as most obstetricians see such cases from time to time. The last which occurred under my care may throw some light on its mode of production.

The patient was a primigravida aged 28 with a slight degree of general contraction of the pelvis, the diagonal conjugate measuring 4½ in. The presentation was an LOA, and she was submitted to trial of labour. This was successful, and after a labour lasting 22 hours, and characterized by strong and regular pains and good co-operation on her part, a living female child, 7 lb. 14 oz., with marked moulding and caput succedaneum, was born at 10 a.m. On the evening of the day of delivery the characteristic crepitus of surgical emphysema became apparent beneath the skin of the neck, face, and upper thorax. By the next day it had spread to the shoulders, arms, and costal margins, and on *x*-ray examination the mediastinum was seen to be extensively involved. The emphysema reached its maximum distribution on the 4th day post partum, after which it lessened and became impalpable on the 9th day, although the radiological appearances of the mediastinum were not normal until the 14th day.

This case would seem to indicate that it is a ruptured pulmonary bulla which permits the entry of air into the interstitial tissues of the lung, whence it passes to the neck and adjoining regions via the mediastinum. So far as I know, no harmful effect results from the condition, though transitory cyanosis and dyspnoea have been noted.—I am, etc.,

Stockport. C. W. F. BURNETT.

Collapse Therapy

SIR,—I agree with much of what Dr. Patrick Heffernan has to say in the last paragraph of his letter (May 8, p. 581), but from his opening remarks I gather that his experience has been unfortunate. Most of us will not agree that the number of cases of tragic results following artificial pneumothorax is appalling.

Dr. Heffernan states that "at one time not so long ago" I abandoned the procedure of adhesion section. May I take this opportunity of correcting him. I am a strong upholder that whenever adhesions are interfering with the effectiveness of A.P. collapse the intrapleural condition should be examined through a thoracoscope, and the adhesion divided if benefit is likely to ensue.—I am, etc.,

Ruthin, North Wales. H. MORRISTON DAVIES.

SIR,—Lest the thought be disseminated that there is general uneasiness about the value of the widespread use of artificial pneumothorax in the treatment of pulmonary tuberculosis, one cannot let Dr. Patrick Heffernan's letter pass without comment.

Our lamented friend Dr. Chandler is beyond the reach of controversy, but my distinguished colleague, Mr. Morriston Davies, has hitherto lacked neither the ability nor the inclination to speak for himself, and it would be a superfluity if not an impertinence on my part to take up the cudgels for him and explain why he abandoned "at one time" collapse therapy or whether it was because of the complication mentioned in Dr. Heffernan's letter.

Far from there being too much "physical interference" in many sanatoria throughout the country, there is not nearly enough. Artificial pneumothorax, adhesion cutting, and other measures such as extrapleural pneumothorax and thoracoplasty, may not be without their risks, but the risk of not doing them is far greater. Patients are allowed to rot behind the walls of sanatoria quite as surely, although perhaps more pleasantly, than did general patients in the dreary wards of medieval lazar houses. Ask the superintendent of a modern sanatorium to give some simple statistics of what happens to patients possessing cavities where no pneumothorax has been done or where an unselective collapse has been produced. Without further "physical interference" (for instance, before the time when division of adhesions was introduced at the North Wales Sanatorium) my own survey showed that 90% died within five years, and about 80% in less than this time.

The subject is far too big to discuss adequately in the scope of one letter or one article. Time spent in one of the progressive sanatoria where the medical superintendent and his assistants confer freely with the visiting surgeons will convince the observer that the invigorating breezes of carefully assessed and planned "physical interference" stimulate and revivify everyone concerned, and dissipate the miasma of inertia and complacency that all too often settles down upon and suffocates those whose lives are spent in the administration of sanatoria and the care of tuberculous patients.—I am, etc.,

Liverpool. HUGH REID.

*** This correspondence is now closed.—ED., *B.M.J.*

Unity in the Profession

SIR,—Dr. Donald Watson (May 8, p. 579) revealed an attitude which is very worrying. Because he considers that certain members of the medical profession are "of a different ideology" from that to which he considers he belongs, he wishes that their right to express their views as doctors be suppressed. In fact, he wishes to "liquidate" them politically in order to gain his own ends. One of the most undesirable features of Nazism is its practice of "liquidating" its opponents in order to gain its own ends—a practice which most thinking people deplore. Is it possible that Dr. Watson's desire to render salaried medical officers politically sterile is a reflection of their political virility?—I am, etc.,

E.M.S., Sector 6, London. H. E. VICKERS.

The Government's Proposals

SIR,—It was a real tonic to be present in the Great Hall at B.M.A. House on May 16 to hear Dr. Charles Hill deliver his masterly survey of the present position in the talks now going on between the Minister of Health and representatives of the profession. On account of leakages of information which have appeared from time to time in the national press, it was only right and proper that a full and frank statement should be given to those people most intimately concerned.

It is unthinkable that the profession should be governed by the local authority; I cannot imagine a worse arrangement. This speech will go a long way towards clearing the air, and will demonstrate to the profession that the three things most needed now are clarity of thought, decisive action, and, above all, unity of purpose.—I am, etc.,

West Harrow. E. W. MEURIG WILLIAMS.

SIR,—At the meeting of the Metropolitan Counties Branch of the B.M.A. on May 16 Dr. Hill made a clever speech and played skilfully on the prejudices—political and others—of that large gathering. The Government's proposals are tentative only, and admittedly many details, especially in regard to administration, leave room for adjustment and modification. Taken as a whole, however, these proposals constitute a new charter of life for the profession. They would lift medical practice out of the mire of commercialism and they would for the first time enable doctors to engage in their noble profession without the distraction of money considerations or the urge of pecuniary gain and profit.

On the financial side, too, the Government's proposals are adequate and even generous. I have no hesitation in asserting that, judged purely on their merits and freed from political bias and sectional influences, these proposals would be welcomed by the large majority of medical practitioners as greatly to their advantage and in every way an improvement on the present conditions of work and remuneration. There is indeed one particular freedom which would be appreciated by all of us more than any other so-called freedom, and that is freedom from anxiety, insecurity, or financial and business entanglements in our daily work.

We of the rank and file are looking to the B.M.A. for guidance, and we expect that guidance to be liberal in outlook and free from diehard irreconcilable bigotry. In face of the present great issues which are bound up with the life-work of every one of us, the B.M.A., in taking up an uncompromising attitude to the proposals made by the Government, is doing the public as well as the profession a great disservice. In a matter so vitally affecting the well-being and conditions of work of every one of us, I suggest that the B.M.A. should abstain from one-sided propaganda. Let a plebiscite be taken from the profession on the particular and specific issues involved, and let every one of us have the choice of free reflection and free decision.—I am, etc.,

London, N.W.6. SAMUEL GRASSE.

Hans Selye and S. Albert (*Proc. Soc. exp. Biol.*, N.Y., 1942, 49, 227) find in experiments on rats that androstenediol and pregnenolone, when given with testosterone, prevent the atrophy of the testis which is produced by small doses of testosterone alone. They point out that the gonad-protecting power of a steroid is independent of its testoid action.

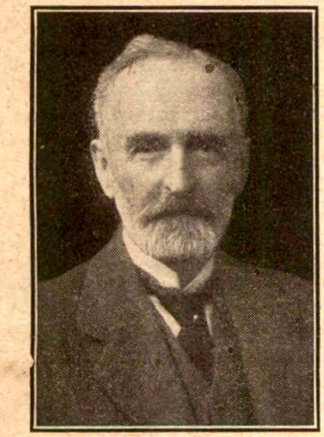
Obituary

SIR ARTHUR NEWSHOLME, K.C.B., M.D., F.R.C.P.

Formerly Principal Medical Officer, Local Government Board

A distinguished career in public health is recalled by the death on May 17 of Sir Arthur Newsholme, who was Principal Medical Officer to the Local Government Board until its absorption in the Ministry of Health.

Arthur Newsholme, a Yorkshireman from the Pennines, was born in 1857. His father, who had been churchwarden at Haworth to the Rev. Patrick Brontë, father of Charlotte, Agnes, and Emily, died when Arthur was a young boy, but his mother's prudence in straitened circumstances enabled him to receive a grammar school education, and he matriculated at sixteen. Afterwards he became dispenser and assistant to a Bradford doctor, and in 1875, with the help of a small legacy, he paid his entrance fees at St. Thomas's Medical School. Realizing the importance of registering quickly, he took the L.S.A. after three and a half years' training, in 1880 obtained the London M.B., and a year later the M.D., qualifying for gold medal.



Press Portrait Bureau.

After service in some hospital posts he started in private practice in Clapham, and in 1884 was appointed part-time medical officer of health for that parish or subdistrict, his salary being £80 a year. In 1888 he was chosen from among fifty candidates for the post of M.O.H. for Brighton. The salary was £500, which was less than the proceeds of his growing practice, but public health work fascinated him. When he left Brighton nineteen years later his salary was £1,000. In the largest seaside town in England his energetic work in such matters as the prevention of milk epidemics, control of scarlet fever, diphtheria, and typhoid fever, earlier administrative control of tuberculosis, and care of infancy and childhood marked him out among his fellows, and in 1908 he transferred his activities from local to central administration.

John Burns, who had become President of the Local Government Board in 1905, had a great admiration for Newsholme, and quotations from the reports of Brighton's medical officer of health, especially on the social aspects of the health of the child, figured from time to time in Burns's public speeches. Presently Burns asked him if he would be a candidate for the position of Principal Medical Officer to the Board, shortly to be vacated by Sir William Power. Thus Newsholme came to the desk first used by Sir John Simon. He left Brighton amid many expressions of regret.

During his period in Whitehall three great additional services were initiated and developed, largely with the aid of Treasury subsidies—namely, maternity and child welfare schemes, tuberculosis medical services, and the special service for venereal diseases. Maternity and child welfare was always close to Newsholme's heart. In taking part in the forward movement to that end during his earlier years at the Local Government Board he prepared four special reports which were national studies of the whole subject. He was active also in the creation of the tuberculosis services, and attended as Government representative an international congress at Washington on this subject.

Coming changes in public health administration were casting their shadows before. On the day before he took up his appointment at the Local Government Board Newsholme gave evidence before the Royal Commission on the Poor Law. One passage from his evidence is noteworthy: "It seems to me necessary, for the maximum economy as well as efficiency, that every man should have the right to call for gratuitous diagnosis, treatment, and provision of medicine." That was several years before contributory sickness insurance, with medical attendance, as a kind of halfway house to the goal, had appeared above the horizon. Newsholme was at the Local Government Board during the passage of the National Health Insurance Bill. The war of 1914-18 was a harassing time for his Department, itself in the throes of change. Looking back on the war, he saw as a relatively slight offset to its overwhelming devastation the intensification and hastening of scientific investigation and its applications which had resulted, and he rejoiced in the immense impetus given by the war to direct work on behalf of mothers and infants. He resigned his post in Whitehall in February, 1919, a few months after the armistice and just before the coming into force of the Ministry of Health Act. His last year of office was marked by the epidemic of influenza, which in its world-wide incidence claimed as many victims as the war itself.

Immediately after his retirement Newsholme travelled to the chief cities of the United States, attending a series of conferences to promote child welfare, and he remained in Baltimore to lecture on public health administration at Johns Hopkins University and to inaugurate a new school of hygiene and public health. During this visit to America he learned, at the age of well over sixty, to drive a car, and wrote amusingly of his adventures on the American roads. One signpost which he saw gave him his text for future addresses on preventive medicine. It reads: "Say it with brakes and save flowers." During his travels in America he came into close touch with American pioneers in public health, and himself undertook a large programme of public speaking. This was not always in university halls. Another labour in still later years was a survey of medical work in various European countries; this took him into Italy, Hungary, Yugoslavia, Poland, and Scandinavia. Then came a visit to Soviet Russia; on his return in 1933 he collaborated in the writing of a book entitled *Red Medicine*. His own impressions of Russia at that time were very mixed. He saw it with some misgiving "going baldheaded" into a completely socialized medicine, a policy and action towards which nearly every Western country was advancing but by slow degrees.

Among other positions which Sir Arthur Newsholme filled at various times were those of examiner for the Universities of Oxford, Cambridge, and London. He was Milroy lecturer to the Royal College of Physicians in 1895, and he served on the interdepartmental committees concerned with tuberculosis and with dental registration and on the Army Sanitary Committee. From 1910 until 1919 he was a member of the General Medical Council. He was president of the Society of Medical Officers of Health in the opening year of this century, and first president of the newly formed Section of Epidemiology and State Medicine of the Royal Society of Medicine in 1907, when his presidential address was on poverty and disease as illustrated by typhus fever and phthisis in Ireland. He was made Companion of the Order of the Bath in 1912 and Knight Commander in 1917. He was a prolific writer, and in the section of public health of any medical library several volumes bearing his name will be found on such subjects as medicine and the State, vital statistics, the prevention of tuberculosis, and the evolution of preventive medicine; while papers from him on the history and affinities of rheumatic fever, the origin and spread of epidemic diphtheria, vital statistics of Peabody Buildings, a national system of notification and registration of sickness, the spread of enteric fever by sewage-contaminated shellfish, the causes of reduction in the death rate from phthisis, and a score of other subjects testify to his alert and interested mind.

He married in 1881 Miss Sara Mansford, a Lincolnshire lady. She died in 1933. Their marriage was ideally happy. Lady Newsholme was her husband's companion in his travels and collaborator in his work. She was herself a speaker of considerable ability.

Sir ARTHUR MACNALTY writes:

It is thirty years since I entered the Local Government Board as a medical inspector and was welcomed by Sir Arthur Newsholme. We were a small and happy medical fraternity in those days, and each one of us was in close relation with our chief. He never spared himself, and he was always ready to discuss our problems with us and to give us the fruits of his long experience. In the ten years that Sir Arthur was Principal Medical Officer he laid the foundations of the national health services, which have so greatly expanded in recent times. He planned and organized the medical side of the tuberculosis, the maternity and child welfare, and the venereal diseases services. All this he did in spite of the interruptions to progress enforced by the war of 1914–18. He made a notable contribution to the war effort by seconding some members of his staff to the War Office to effect close liaison between the military and the local authorities in the provision for camps and hospitals and the treatment of epidemic disease. When the Ministry of Health was established and he left the public service he had the satisfaction of knowing that others would carry on the work which he had ably begun. In the years of retirement his facile pen was seldom idle, and he visited many countries in order to study health conditions and to advise on their problems. Newsholme had much affection for the people of the United States and greatly admired their work in medicine. He lectured at Johns Hopkins University and always welcomed Americans in his English home. His physical powers only waned within the last two years, but his mental energies were unabated. A charming host and a witty talker, he was always interested in his old colleagues and the progress of public health and medical work. Above all he was a good man who earnestly desired to leave the world better than he found it. Newsholme's name will ever be writ large in the history of public health.

We regret to record the death in his 77th year of Dr. William Summerskill of Blackheath, father of Dr. Edith Summerskill, M.P. for West Fulham. He studied medicine at Leeds and at St. Mary's Hospital, London, and had been a member of the British Medical Association continuously since 1889. When Dr. Summerskill qualified some 54 years ago, writes E. J. S., his first appointment in his native Yorkshire was one which had previously been filled by a coachman. He retained no reverence for those exciting days in medicine, although they provided him with a wealth of grim memories. The growth of medical science was most fascinating to him, and he was never known to miss reading the *B.M.J.* from cover to cover. Apart from a passion for travel and literature, he was completely absorbed in medical practice, in which he was extremely active until his heart began to fail last year. He refused to recognize the seriousness of his illness and saw patients almost until the end.

Medical Notes in Parliament

In moving the thanks of the House of Commons on May 18 to all ranks of the victorious Forces in Africa Mr. Attlee said he must mention the work of the medical service, of the doctors, the nurses, and all the non-combatant services. The motion was carried unanimously, as was a similar one moved in the House of Lords on the same day by Viscount Cranborne.

Food Supplies for Greeks

Mr. Harvey asked on May 11 whether the Parliamentary Secretary to the Ministry of Economic Warfare could give information of the shipment of food supplies, especially of dried milk and vitamins for children, which were being sent to Greece; and whether the neutral authorities supervising their distribution continued to be satisfied that no abuse had occurred.

The Ministry's spokesman said that food supplies which had reached Greece during the last three months comprised 28,703 tons of wheat, 8,561 tons of pulse, and 1,096 tons of condensed milk. Further shipments which had left Canada but which had not yet arrived at Greek ports included approximately 32,000 tons of wheat, 6,000 tons of pulse, and 600 tons of condensed milk. It was not yet known whether these cargoes included vitamin tablets, though their inclusion had been agreed to. As regards the state of nutrition in Greece, recent reports had shown a considerable improvement as compared with a year ago, especially in Athens.

Sir Frank Sanderson asked on May 19 whether the Government would permit dried milk and vitamin concentrates to be sent to Greece, France, Belgium, and Poland to provide children under 16 and nursing and expectant mothers with a daily ration sufficient to ward off the worst deficiency diseases, seeing that the money, supplies, and shipping were available, and that the International Red Cross would be able to provide for full control of the distribution.

It was stated in reply that, after the fullest consideration and with the deepest sympathy for the Allied peoples of Europe, the Government were convinced that a general action of the kind described would inevitably be exploited by the enemy for his own advantage. Moreover, such action could hardly be confined to the countries named in the question, and the provision of foodstuffs for children and nursing and expectant mothers throughout occupied Europe would involve a very serious breach in the blockade.

Bread and Milk

Opening a discussion on May 13 about the work of the Ministry of Food, Mr. Mabane said the national milk scheme and the milk in schools scheme had increased the consumption of liquid milk far above the peacetime level. The claim of children and expectant mothers on milk came first. That was not their only priority. Whatever they needed for an adequate and full diet Lord Woolton was determined to supply. That attitude had the full support of Parliament. Stringency demanded that the nation should squeeze the last calorie and the ultimate vitamins out of the food it had.

Mr. David Adams complained that there was no Government Department charged with seeing that the milk supply was pure. In London diseases which were milk-borne occurred despite the general pasteurization of milk there. That was due to mishandling of milk which had been properly pasteurized. Recently Prof. Ryle had visited Newcastle during his survey of hospitals for the Ministry of Health. He had said that in Cambridge his children had been affected by milk-borne diseases. The milk was said to be pasteurized but the apparatus was found to be antiquated and the milk was not really pasteurized. Newcastle-upon-Tyne Corporation found in 1942 that 24.1% of designated milk was unsatisfactory on bacteriological tests and 33.2% undesignated milk. In the North of England tuberculosis was on the increase among children.

Sir E. Graham-Little said that in most parts of the country 95% of the food of the larger part of the population consisted, by quantity, of bread. The loaf was of a heterogeneous composition and of no fixed standard. Of the germ which was extracted 99% was applied to proprietary articles. He appealed to the Ministry to raise the extraction percentage from wheat. Ten other diseases beside tuberculosis were constantly carried by milk. The next in frequency to tuberculosis was undulant fever. Last year 500 cases had been reported. These were a mere fraction of what occurred. This was an insidious complaint, seldom diagnosed. Something like ten milk-borne diseases were not revealed by the tuberculin test. Pasteurization was necessary to protect the public pending the production of milk which was free from a number of infections.

Mr. Mabane said the demand was not adequate to enable all T.T. milk to be sold as such. It was not the case that medical officers of health had been deprived of some right they previously had to reject milk. Consumers could purchase whatever type of milk which the supplier with whom they were registered provided, but if he did not provide T.T. milk they were not permitted to transfer their registrations to another dairyman in order to obtain T.T. milk. Efforts were being made to encourage and to assist dairymen to provide T.T. milk for customers who required it.

In an earlier debate Mr. Mabane had said that it was not in the national interest to publish the total gallons of milk consumed daily, but that from 60 to 65% was pasteurized. Milk supplied to schools did not all fall within one category, but must be approved as to source of supply and quality by the appropriate medical officer of health.

Protection of Practices Scheme

Mr. Groves asked on May 13 how the Minister of Health proposed to reconcile the protection of practices scheme with the Medical Benefit Regulations and terms of service, having regard to the limitation of lists, the obligations upon deputies and partners, and the responsibility of the practitioner for the insured persons whose names were included in his list. Mr Ernest Brown answered that under the National Health Insurance (Medical Benefit) Amendment Regulations, 1942, doctors who undertook to attend the insured patients of another doctor during the latter's absence on whole-time national service, under a voluntary protection of practices scheme, had the responsibilities of principals as well as deputies in respect of those patients. The provisions of the Medical Benefit Regulations and terms of service as to limitation of lists and deputies and partners accordingly applied, including provision for augmentation of the lists with the Minister's consent. In the case of statutory schemes a practitioner attending absentee practitioners' patients was in the position of a principal to whom the provisions of the Regulations and terms of service similarly applied.

Regulation 33B

Replying on May 13 to Dr. Summerskill, Mr. Brown said information received from all but a very few authorities in England and Wales showed that 36 men and 475 women had been reported to medical officers of health as alleged sources of venereal infection, of whom 1 man and 27 women had been the subject of more than one report, which was necessary before Regulation 33B could operate. Of these 28 persons two women had refused treatment, one expressly and one by default, and had been prosecuted and imprisoned. No civilian voluntarily undergoing treatment for venereal disease was subject to compulsion to complete it. He did not agree that the Regulation operated unfavourably against women.

Food Rationing Advisory Committee

Sir JOHN ANDERSON said on May 18 that the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council had held fourteen full meetings in all. Owing to the decrease in the number of questions referred to the committee, and particularly of questions involving new principles, it had not so far been necessary to convene a full meeting in 1943, although a subcommittee met. Minor questions arising between meetings were circulated in the form of memoranda and the opinions of members obtained in writing. The other bodies consulted on behalf of the committee since the beginning of this year, in addition to Government Departments specially concerned, were the Royal College of Obstetricians and Gynaecologists, the Joint Tuberculosis Council, and the Tuberculosis Association.

Notes in Brief

Mr. Brown has recently taken the opportunity of asking local authorities to concentrate attention upon cleanliness in methods of production, treatment, and distribution of milk.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week there were considerable fluctuations in the trends of infectious diseases. Rises occurred in the incidence of whooping-cough 585 and dysentery 58, but decreases were reported for measles 3,014, scarlet fever 225, acute pneumonia 161, cerebrospinal fever 25, and diphtheria 24.

Measles was down by 351 in Glamorganshire, 260 in Lancashire, 259 in Derbyshire, 215 in Essex, 210 in Kent, 177 in Suffolk, 165 in London, and 109 in Yorks West Riding. A few counties recorded a rise in incidence, the largest being Wiltshire 29, and Northumberland 28.

The downward trend of whooping-cough during the past month was interrupted by a sharp rise to the highest level of the past 20 months: though greatest in the North, it was general throughout the country. The largest increases were recorded in Lancashire 131, Yorks West Riding 67, Warwickshire 54, Derbyshire 27, London 27, Staffordshire 26.

The notification figure for scarlet fever touched the lowest level for 9 months. The biggest variations within the counties were decreases in Surrey 29, London 27, Staffordshire 26, Cheshire 24; and a rise in Essex of 20.

For the fifth consecutive week diphtheria has continued to decline slightly, and this disease is now at the lowest level since last August. The biggest reductions were in Yorks West Riding 32, Durham 26, Gloucestershire 20; whilst the largest increase was that of Lancashire 33.

A further large rise in dysentery, 58 cases, was reported, and the total is now three times that of a fortnight ago. Fresh outbreaks occurred in Lancashire, Blackburn C.B., 33 cases, and Essex, Chelmsford R.D., 22 cases; and in Staffordshire, Stoke-on-Trent C.B., where 45 cases were reported last week, there were 61 new cases.

In *Scotland* notifications of measles rose from 340 to 657, and of whooping-cough from 145 to 350. The city of Glasgow recorded a rise over the preceding week of 290 cases for measles and 169 for whooping-cough. In Edinburgh 84 cases of measles, a drop of 20, were notified.

In *Eire* diphtheria notifications fell considerably, and the total of 70 recorded was the smallest weekly total during the present year.

In *Northern Ireland* notifications of measles went up from 38 to 88: 71 were recorded in Belfast C.B. and 17 in Lisnaskea R.D., where a large outbreak of 207 cases was reported during the week ending April 10.

The Week Ending May 15

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 1,748, whooping-cough 2,106, diphtheria 602, measles 8,032, acute pneumonia 712, cerebrospinal fever 62, dysentery 98, paratyphoid 4, typhoid 4.

No. 18

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 8.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

---

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Paratyphoid A and B now notified separately in Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

The next meeting of the Biochemical Society will be held in the Department of Medical Chemistry, Edinburgh University, on Saturday, June 5, at 2.30 p.m. Tea at 4.30 p.m.

A one-day conference on casualty service has been arranged by the Citizens' Guild for Civil Defence for Thursday, June 10, at Victory House, Leicester Square, W. The address of the Guild is 20, Buckingham Street, Strand, W.C.2, and tickets for the conference may be had from the secretary.

The next meeting of the Liverpool Medical Institution on June 3 at 4.30 p.m. will be devoted to surgery of the chest. Dr. Robert Coope and Mr. Morriston Davies will read papers upon the early recognition and diagnosis of and possibilities of intervention in diseases of the lungs, with special reference to bronchiectasis and carcinoma. Between 4 and 4.30 a number of specimens collected and presented by Dr. Joy Cronin Lowe and Mr. Ronald Edwards will be displayed. Tea at 4.15 p.m At the conclusion of the meeting Mr. Hugh Reid will show a colour film illustrating an operation for lobectomy.

At a meeting of the Physical Society on Friday, June 4, at 5 p.m. in the Lecture Theatre of the Science Museum, Exhibition Road, S.W.7, Prof. F. C. Bartlett, F.R.S., will give the Thomas Young Oration on " Some Current Problems in Visual Functions and Visual Perception."

A sessional meeting of the Royal Sanitary Institute will be held in the National Museum of Wales, Park Place, Cardiff, on Saturday, June 5, at 10.30 a.m.

The Medical Research Council of Ireland (address: 85, Merrion Square, Dublin) has awarded grants to Dr. Stephanie Whelan, Dr. H. E. Counihan, Dr. S. J. Boland, Dr. N. Falkiner, Drs. F. Geoghegan and E. de Valera, Dr. P. L. Brennan, and Prof. W. J. E. Jessop; and seven earlier grants have been renewed for further periods.

Dr. T. A. Divine, Malayan Medical Service, has been officially reported prisoner at Singapore, and Dr. R. S. Hardie of Kuala Lumpur, F.M.S., prisoner of war in Thailand. Dr. O. E. Fisher of Fryston, Castleford, and of the Malayan Medical Service, is safe and in Japanese hands on Singapore Island.

Local authorities are required by the Ministry of Health (Circular 2818) to make a return of their public health and school medical staffs, to notify the Minister of vacancies, and to get his approval before they fill a vacancy and of the candidate proposed. It is pointed out that doctors engaged whole-time in public health and school medical work who are of military age are reserved in the posts they now hold, and if they wish to apply for other posts they must first obtain the Ministry's permission. Similar permission is necessary in the case of married women who, if they were not married, would be liable for military service. Written application for permission should be sent through the Regional Medical Officer of the civil defence area in which the doctor is working. Local authorities' advertising vacancies in the *Journal* are asked to indicate that the appointment advertised has been approved by the Ministry.

A cancer centre is to be developed at the London Hospital, Whitechapel, from the deep therapy department.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College held on May 18, with Mr. J W. Struthers, President, in the chair, the following, having passed the requisite examinations, were admitted Fellows:

R. C Baird, D B. E. Foster, R C J Hill, R C Howard, R. V Liddell, A. R. Murray, G. N MacFarlane, C. B. O'Carroll, T. E. Rutter, R. A. Smith, D. C. Wiseman.

The Henry Arthur Dalziel Ferns Bursary was, after a competitive examination in organic chemistry in its application to medicine, awarded to Thomas Dale.

The Bathgate Memorial Prize was, after a competitive examination in materia medica and therapeutics, awarded to A. M. Kinghorn.

Correction.—In our announcement of the conferring of the honorary degree of D.Sc. by the University of Oxford on Dr. Joseph Trueta, the Wingfield-Morris Orthopaedic Hospital at *Headington*, near Oxford, was wrongly described.

The Services

CASUALTIES IN THE MEDICAL SERVICES

Capt. **William Richard Cyrlas-Williams**, who is reported as killed in action in North Africa, was the youngest son of Mr. and Mrs. W. Cyrlas-Williams of Porthcawl. He studied medicine at Cambridge and at University College Hospital and qualified M.R.C.S., L.R.C.P. in 1941, soon afterwards receiving a commission in the R.A.M.C. His widow is Dr. Ruth Cyrlas-Williams.

Reported Missing.—Capt. G. S. Hodge, R.A.M.C.

Missing, Singapore, now Officially Reported Prisoner of War, Thailand.—Capt. V. W. J. Hetreed, R.A M.C.

Killed in Action in Tunisia.—Lieut. G. F. Barnes, R.A.M.C.

Missing, Presumed Killed.—Temp. Surg. Lieut. T. P. Storey, D.S.C., R.N.V.R.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Normal Temperature Range

Q.—*A patient continually records a temperature of 99.4° to 99.6° F. taken in the late afternoon or early evening (4.30 p.m. to 5 p.m.). Can this be looked upon as being a normal temperature for this patient? Below what level is a temperature considered as being pathologically subnormal?*

A.—The limits of the daily rhythm of body temperature were set by Gessler in 1928 at 36.5° to 37.5° C., which is equivalent to 97.7° to 99.5° F., and since then these values have been pretty well established. These values were obtained with a deep rectal thermometer, and they are approximately one degree higher than those obtained by placing a thermometer in the mouth. The lowest temperature is found between 2 and 4 a.m., and the highest in the early afternoon. The latter persists from about 1 to 7 p.m. and is usually found again at 11 p.m. Two groups of people appear to be exceptions to this rule: first, newborn babies, who have a much smaller diurnal range; and, secondly, the very aged, whose mean value is lower and in whom the daily rhythm may be reversed. The variations appear to depend more on the absolute time than the occupation, and are obtained even when more sleep is taken by day than by night Strenuous exercise causes a temporary rise in body temperature of from 1° to 4° F. If the temperature of the patient in question was taken by mouth, it must be regarded as abnormal and must be attributed to some degree of toxaemia, even though this may not easily be detected by other means.

Signs of Spinal-cord Constriction

Q.—*If a constriction, such as an organizing blood clot, were applied to the spinal cord, which cells or tracts would be likely to be affected first?*

A.—This is a most important question. Clinical misdiagnoses in cases of compression of the spinal cord may occur in the early stages, just when operation is most required and radical cure most possible. Many medical men assume that a sharp " sensory level " is always an early and constant sign of spinal-cord compression and do not think of this diagnosis unless they find such a level. Sensory loss below the level of compression is a constant sign only at a comparatively advanced stage; as a result, successful removal of the cause of compression gives only too often a disappointingly small amount of relief. When the cord is subjected to a generalized pressure all round its circumference, at one level, and this pressure slowly increases, then the tracts which are nearly always first affected are the pyramidal, with the insidious appearance and progression of spastic paraplegia. There may for a long time be no sensory changes, so that a misdiagnosis of some progressive system disease such as disseminated sclerosis, amyotrophic lateral sclerosis, or subacute combined degeneration, may be made. As the pressure increases the afferent tracts, the posterior columns, usually succumb next. They commonly do so in a characteristically peculiar way that may deceive the clinician—namely, in an ascending manner, so that the lowest part of the body is first affected. This may lead to some form of ascending infection being thought of, such as polyneuritis or ascending myelitis.

The moral is that whenever a case of spastic paraplegia without sensory changes and of insidious onset and with a tendency to progression is seen, of which the cause is not obvious, then cord compression from some such cause as tumour or granulomatous infection should at once be thought of. Fortunately, a rise in cerebrospinal-fluid protein often confirms the diagnosis, but it may be necessary to perform myelography by cisternal injection of lipiodol to determine the level of compression as well as to confirm the diagnosis, and no hesitation should be felt about carrying this out.

It should be remembered that in some cases of compression sensory roots may be involved at the level of the lesion, giving rise to root-pains of a segmental distribution at this level. These pains can be very deceptive, and, as they are a very early sign, they should not be overlooked. Many a case has been diagnosed in the past as fibrositis, neuritis, or even neurosis, and valuable time has been lost. Also there is no more deceptive syndrome in medicine than compression of the cauda equina in its early stages. The bladder is frequently paralysed early, and retention of urine may be the first symptom. A misdiagnosis of hysteria has sometimes been made in these cases. A first sign may also be uni- or bi-lateral sciatica as a form of sciatic root irritation.

Diet for Catarrhal Jaundice

Q.—*A child aged 9 years has catarrhal jaundice. I am at my wits' end to know what to advise the parents to give the child to eat. As you no doubt are aware, fish, chicken, and eggs are almost unobtainable. Can you suggest a suitable wartime diet for such cases?*

A.—The essential feature of the diet in catarrhal jaundice is reduction of the fat intake. For this reason eggs are undesirable. The modern tendency is to give a diet high in protein as well as in carbohydrate, and casein is regarded as particularly valuable. There is a suggestion that vegetable protein is better tolerated than animal protein, but it is doubtful if the prejudice against butcher's meat has any real foundation. Skim milk and "household milk" should be given generously in the form of potato and vegetable soups, or with cereals, arrowroot, and other farinaceous foods. Fruit and fruit drinks should also be used as freely as they are available. Glucose may not be well tolerated during the stage of nausea, and savoury flavours like "marmite" may be appreciated better. As soon as appetite recovers, it should be satisfied with bread and toast, jam, honey, and marmalade, lean meat, vegetables, salads, puddings made with skim milk, etc. Fat should be restricted for approximately six weeks, and it is wise to give liq. vitamin. A & D Conc. *B.P.* ♏ 3–5 b.d., and water-soluble vitamin K (acetomenaphthone) 2–5 mg. daily by mouth during this period to make up for the deficit of fat-soluble vitamins in the diet.

Food Priority for Pregnant Women

Q.—*There is a discrepancy between the practices of the borough and county food offices here with regard to the food priority certificates for pregnant women, and I wonder if you can tell me which is in accordance with the regulations. One insists on a fresh medical certificate every three months, and the other grants the expectant mother renewals every three months without any further certificates from the doctor. The officials at the former office say quite definitely that the regulations do not allow them to renew the expectant mother's priority milk permits, etc., without a new doctor's certificate.*

A.—The maximum period of validity of the first medical certificate to a pregnant woman entitling her to priority supplies of food is three months. Authority for the supply of these foods may be renewed for an additional period of three months until approximately one month after confinement on the production of a further medical certificate. A fresh medical certificate is therefore necessary every three months.

Chromosomes in Nerve Cells

Q.—*All textbooks I have consulted make the general observation that chromosomes are present in every somatic cell. Can it be definitely stated, however, that these bodies exist in the cells of the human brain and nervous system? It may be that, as with the nuclei of red blood corpuscles in man, they are present in earlier, but not in later, phases of development of the nervous system. If this is so, at what stage in the ontogenetical evolution of neurons do the chromosomes disappear?*

A.—Chromosomes can seldom be made visible except during nuclear division. Nerve cells do not divide later than the germinal stage; mitosis is never seen in neurones. Once the stage at which division can occur has passed, therefore, it is not possible, in the present state of knowledge, to discover whether the chromosomes of the nerve cell nucleus still exist as such or whether a process of regression takes place. As is pointed out in the question, this is not unusual once a cell has passed the reproductive stage and become specialized to perform a particular function.

LETTERS, NOTES, ETC.

Changing the pH

Dr. B. H. SHAW (St. Mawes) writes: Dr. Richard Kerry in his letter on changing the pH (April 24, p. 521) suggests that shock may be due to excess of potassium in the blood. Is it not more probable that the excess of potassium in the blood may be the result of shock? A. V. Hill states ("Chemical Transmission in Nerve," Liverside Lecture, 1932) that "when a nerve is stimulated to fatigue, K escapes during and for some time after stimulation," and suggests that the surface is rendered permeable during activity; Horton (1930) found that in an excess of potassium, muscle was much less irritable. Clinically, I have found very considerable benefit resulting from the use of potassium chlorate (5-gr. tablets dissolved in the mouth, night and morning) in states of anxiety and early schizophrenia, also in relation to the sedative effect of K on muscle irritability, good results following similar administration in bladder troubles so frequent in old people with prostatic enlargement.

Thirst at Sea

Surgeon Rear-Admiral V. G. THORPE writes: Apropos of our correspondence two years ago, and your note on "Thirst at Sea" in the *British Medical Journal*, July 26, 1941, I have the honour to draw your attention to an article in the May number of the *Reader's Digest* entitled "Survive at Sea by Eating and Drinking Fish." The writer (American) states that the raw flesh of a freshly caught fish contains a large quantity of a watery fluid which can be squeezed out of it by pressure or by wrapping it in a clean napkin and twisting the ends. It is a pink liquid, and tastes sweet, with only the slightest suggestion of fish about it. Two seamen volunteered to drink no water for ten days and live for that time on ordinary "abandon ship" rations and fish juices. They came through the test in perfect health. Alternatively the raw flesh can be chewed, and the solid matter rejected, which is the method the natives of Tahiti adopt. Apparently the United States Navy is taking up the idea, and is ordering life-boats and rafts to be fitted up with fishing tackle, nets, etc., so that no one in future need die of thirst so long as they have the means to catch fish.

Inaccurate Report in Newspaper

Prof. H. J. SEDDON (Clinical Director, Wingfield-Morris Hospital, Oxford) writes: On two occasions within the last six months the work of the Oxford Peripheral Nerve Injury Centre has been the subject of inaccurate articles that appeared in the lay press. On the first occasion the information was obtained through a hospital servant. On the second (May 13) we have not yet been able to trace how or when the reporter gained access to the hospital. The effect of these articles, published without the knowledge, consent, or approval of the hospital authorities, has been singularly unfortunate. People with all sorts of irremediable nervous disorders are writing asking for consultation or treatment.

Tanning for a Skin Lesion

Dr. L. WERTHEIM (Ashton-under-Lyne) writes: With reference to the letter on tanning for a skin lesion, by Dr. K. A. McCaughey (April 24, p. 519), it might be of interest to recall that the astringent effect of tannic acid on vesicular and "weeping" lesions of eczema (and dermatitis) has been known to dermatologists many years before the drug came into general use for burns. The late Prof. S. Ehrmann of Vienna, to whose school I had the privilege to belong, always recommended tannic acid as an excellent desiccant for certain types of eczema. He applied it in a 2% aqueous solution, occasionally also in a lotion or ointment. When in recent years preparations such as tannin jelly, etc., were introduced for the treatment of burns, I had no hesitation in taking advantage of their most convenient properties and in using them for the treatment of weeping eczema. The results were highly satisfactory in both infants and adults, especially in cases of weeping peri-anal eczema in babies.

THE OPHTHALMOSCOPE IN CLINICAL MEDICINE

THE INTERIOR OF THE LIVING EYE CONSIDERED AS A BIOCHEMICAL LABORATORY*

BY

A. MAITLAND RAMSAY, M.D., LL.D., F.R.S.Ed.

Until the ophthalmoscope was discovered the interior of the living eye was *terra incognita* to the physician. The ocular structures deeper than those visible in the anterior chamber were for all clinical purposes a sealed book, and our knowledge of the inner eye and its diseases had to be acquired from the observation and the interpretation of symptoms. That method of procedure is beset with many pitfalls, for it rests almost entirely upon the patient's own account of the disease, and very few of them can give a clear and connected description of the character, the site, and the duration of the symptoms. It is only when the doctor is able to analyse all the patient has told him that he can, by a few direct questions, separate the wheat from the chaff. When he does succeed in so doing valuable information is always obtainable; but the clinical value of such an examination depends almost entirely upon the surgeon's special skill and his personal experience. Nevertheless much useful information has been acquired and accumulated by the careful study of the symptomatology of disease, especially when a knowledge of medicine went hand in hand with literary culture. A striking example of what can be achieved in that way is seen in William Mackenzie's *Practical Treatise on Diseases of the Eye*, in which accurate medical observation is accompanied by such vivid clinical description that the reader almost sees the patient rising from the printed page.

The Clinician and the Laboratory

Clinical observations differ from laboratory investigations in medical practice, inasmuch as the latter are quite impersonal, whereas the former always regard the patient as an individual entity. That aspect of the position has tended to shrink into the background in recent years owing to the steadily increasing importance that is now attached to intensive laboratory research. In no circumstances, however, can the clinician be replaced by the laboratory worker. In a large number of cases both of them are required if the patient is to have the benefit of the highest medical skill; but when consultation is necessary the clinician must never allow himself to be supplanted by the laboratory worker. In the initial diagnosis of disease the clinician must always take first place. He works beside the patient, and ought to exhaust every means of examination at his disposal to reach a diagnosis by himself, and when he fails he ought always to know the kind of assistance he is requiring before he seeks help from his colleague in the laboratory. The best results are most likely to be got when both workers meet and discuss together the problem they are anxious to solve.

When clinical symptomatology is uncontrolled by objective examination, or by any form of experiment, patients who are not in the same category are apt to be grouped together. For example, before the introduction of the ophthalmoscope patients suffering from failing sight or loss of sight were all included under the general heading "amblyopia and amaurosis" Many attempts were made to reclassify those said to be suffering from amblyopia; but as vision becomes more impaired accurate diagnosis is wellnigh impossible, and when the stage of blindness or amaurosis is reached some with grim humour defined that condition as a state of matters in which the patient sees nothing and the surgeon sees nothing.

The laboratory worker always aims at scientific precision, and concerns himself for the most part with analysis and measurement. He puts his chief reliance upon chemical and microscopical tests, and upon experiments whose results can be tabulated in figures. The clinician requires something more. His education at the bedside has qualified him for dealing with human suffering; consequently he is able to make a character study of the individual patient, and knows how to help him with words of hope and encouragement. Our forefathers paid great attention to the study of human beings both in health and in disease, and they encouraged medical students to cultivate their power of observation and to train their sense of touch, but this personal training of eyes and hands is passing into the background. In these days we must be careful not to neglect the clinical tradition of the personal art and skill of mind and hand, without which a family doctor will find the most up-to-date scientific training in the laboratory insufficient in many of the situations he is called upon to cope with in the daily round of general practice. Modern medicine has become so highly mechanized that a medical practitioner is being tempted to rely more and more on the findings of an instrument and on a report from a laboratory. We are forgetful that the human brain, when it is highly trained, is the finest of all instruments; and when we employ some mechanical apparatus to do its work, and save ourselves the trouble of thinking, we must be careful that we do not sidetrack our own intelligence.

The Laboratory of the Eye

Among the instruments on which a medical student is taught to rely in his clinical work, the ophthalmoscope is in a category by itself. The ophthalmoscope enables us to see the nervous and vascular structures of the fundus oculi and to study physiology and pathology during life. For our immediate purpose we may liken the interior of the living eye to a fully equipped biochemical laboratory, in which Nature herself performs all the experiments. With the help of the ophthalmoscope we can look into this laboratory through the window of the pupil and watch Nature at work; and as Nature's ways throughout the body are everywhere consistent, we are justified in concluding that what we can see in the eye is an index of what is taking place hidden from view in other regions of the body. The fundus oculi therefore affords a unique opportunity for the clinical study of vital processes, and is a convenient place for the clinician to meet the pathologist. In the laboratory of the eye the patient can never be forgotten The pathologist working in his own department examines and furnishes a report on the specimens that have been sent to him, but he does not need to have seen the patient or to be interested in the human aspects of the case; the clinician, however, always has to deal with a patient behind the disease.

---

* An address, illustrated by lantern slides, given to the Bute Medical Society, University of St. Andrews.

Notwithstanding his skill and the perfection of his laboratory methods a chemist's experiments are not invariably successful, and in the laboratory of the human body Nature's experiments are also followed by success and failure. When Nature's experiments are successful we are quite unconscious of the functioning of our bodily organs. Everything seems to go with the precision of clockwork. We have a supreme sense of well-being. We enjoy good health, and feel quite fit for our daily duties. When, on the other hand, Nature's experiments are unsuccessful we at once become conscious of abnormal sensations, which we recognize as symptoms of disease. In some instances an ophthalmoscopic examination enables us to detect disturbance of metabolism in its earliest stages. The physician who neglects the routine use of the ophthalmoscope in general practice misses a great deal. The original models of the instrument were difficult to manipulate, but the modern electric ophthalmoscope enables us to examine the eye as easily as we can take the temperature, auscultate the chest, or apply chemical tests to the urine. Before the medical practitioner can understand what he is looking at, however, he must be able to correlate the ophthalmoscopic appearances with the microscopic anatomy of the fundus oculi. Each of the three tunics of the eyeball contributes to produce the ophthalmoscopic picture of the eye ground. The sclerotic may be regarded as the white canvas on which the picture is painted. The blood in the capillaries of the choroid and retina is responsible for the red colour, while the transparency of the retina gives it a peculiar lustre and characteristic translucency.

The Fundus Oculi

In every organ of the body there is a wonderful adaptation of structure to function. In the eye perfect transparency is the primary requisite, and that has been secured for all the structures especially concerned with vision by an almost complete impermeability of the intra-ocular capillaries to the passage of colloidal substances. In a state of health water, gases, and crystalloids readily escape from the retinal capillaries, but colloids for the most part are retained in the blood. As a result of this retention of colloids a peculiar translucency is the outstanding characteristic of the normal fundus oculi, and at the onset of disease that translucency is the first thing to be lost. The capillaries are very sensitive to the quality of the blood. The least taint of toxaemia causes them to dilate rapidly, and, by damaging the endothelium of their walls, allows colloids to escape. Congestion of its capillaries, and its infiltration with colloids, quickly impair the normal transparency of the retina, which can be recognized clinically by lack of translucency in the ophthalmoscopic appearance of the fundus oculi. Instead of its normal characteristic brilliance the fundus looks like glass which has lost its lustre after having been breathed upon. At the outset the departure from the normal is very slight; but clinically it is one of those variants situated on the borderline separating the physiological from the pathological.

The ophthalmic surgeon occasionally sees those cases among patients suffering from eye strain sent to him by colleagues. All of them suffer from headache due to an error of refraction, and the great majority are at once relieved by the use of suitable spectacles; but a few get no benefit from optical treatment alone. These patients form a group by themselves, and all of them present the pathognomonic sign of lack of translucency in the ophthalmoscopic picture of the fundus oculi. There is no deterioration in the patients' usual acuity of vision, but some complain of attacks of misty sight accompanied by black spots floating in front of the eyes or by sparks and flickering lights dancing in the field of vision. These subjective symptoms are supposed to be due to increase of blood pressure in the central artery of the retina, and although they may be premonitory they are quite distinct from those signs accompanying an ordinary sick headache or an attack of migraine. An important concomitant sign is that although the quantity of urine passed in 24 hours is somewhat less than usual, the specific gravity is not increased in the same ratio, and when a specimen is kept overnight in a urine-glass there is almost invariably a deposit containing numerous minute crystals of calcium oxalate; but there is no interference with the excretion of urea. It is probable that, in the case of those patients, waste products which ought to have been excreted in the urine have been retained in the blood, and have caused a mild form of toxaemia by dilating the capillaries both of the retina and of the glomeruli of the kidney. That hypothesis gave the clue to the successful treatment of those patients. More than 50 years ago a similar condition in general medicine was described by Sir Andrew Clark in his papers on renal inadequacy, and by Charles Murchison in his book on functional derangement of the liver. These authors have demonstrated, from a clinical standpoint, that in both the kidney and the liver the disorder is functional, and that healthy action can be restored by the use of eliminant remedies. When, in addition to the use of the glasses required to correct the error of refraction from which the patients we are considering suffered, a course of eliminant treatment is prescribed relief from the symptoms is speedy and permanent. The normal ratio between urine volume and the specific gravity is restored, the oxaluria disappears, the retina recovers its normal transparency, and the headache is cured.

The Fundus and the General Circulation

The circulation can be studied in the fundus oculi as an integrated whole, and as the circulation of the blood in the eye is governed by the same rules as those which regulate its distribution to every organ of the body it gives a reliable clue to the state of the general circulation. The intra-ocular circulation is peculiar inasmuch as it has to be carried on under the pressure of the intra-ocular fluids, and the smooth steady flow of blood throughout the retina depends upon an accurate balance being maintained between blood pressure on the one hand and the pressure of the intra-ocular fluids on the other. By the usual method of ophthalmoscopic examination pulsation is seen in the veins as they pass over the optic disk, but no pulsation is visible in the arteries unless there has been a breakdown in the physiological adjustment of those two pressures. For example, if there is a sudden fall in the diastolic systemic pressure, as occurs in aortic regurgitation, or an increase in intra-ocular pressure as in glaucoma, pulsation in the main branches of the retinal artery can always be seen with the ophthalmoscope. Venous pulsation therefore is physiological, but arterial pulsation is always pathological. The walls of the vessels in a state of health are so transparent that arteries are distinguished from veins by the colour of the blood. When used by the direct method the ophthalmoscope acts as a low-power microscope, and gives a magnification of 15 diameters. We are thus able to see arterioles during life which we cannot see with the unaided eye in a post-mortem specimen.

Ocular Manifestations of Disorders

In what follows I shall limit myself to a consideration of the ocular manifestations of the injurious effects of disordered metabolism upon the cardiovascular–renal system. In the act of living there is a constant manufacture of toxic products, which, if health is to remain unimpaired, must either be destroyed at once or removed from the body with the least possible delay. Our bodily life therefore seems to be very much a matter of chemistry. It is only at the level of the capillaries that exchanges in both directions take place, for the purposes of metabolism, between the blood and the tissues. By that means the physiological processes of assimilation and elimination are conducted and the nutrition of the body is adequately maintained. The capillaries are very sensitive to the presence of impurities in the blood, and high blood pressure is the usual accompaniment of toxaemia due to the absorption of metabolic waste products; but so long as the walls of the blood vessels remain healthy there is little danger of hypertension causing rupture and haemorrhage. That is a fact which should not be forgotten, because so many are said to be suffering from high blood pressure nowadays that the subject is a common topic of conversation far beyond the bounds of the medical profession. As a rule the general trend of all such conversations is unnecessarily gloomy. It is well known that in some families there is a hereditary predisposition to a state of high blood pressure in late middle life; but it is not always remembered that although increase of blood pressure is frequently an accompaniment of advancing years it is not in itself a disease. Very considerable variations are quite compatible with ordinary life and health, and probably also with normal expectation of life. Ellis is of the opinion that in more than 90% of the patients the hypertension is benign. Allbutt describes this condition as hyperpiesia, which often exists unaccompanied by symptoms, and is sometimes discovered in the course of a routine medical examination for life insurance. Those who suffer from a benign form of increased blood pressure ought to be discouraged, therefore, from taking too much interest in their high blood pressure.
